elimination conclusions. Today a definitive match or elimination conclusion is one of practical certainty, or reasonable degree of scientific certainty, not absolute certainty. And other examination-report language is also possible and justifiable. Of course, the nature of the specific case is relevant. For example, if an examiner were presented with a 32-caliber fired bullet with GRCs present, and a 45-caliber fired bullet with GRCs present, she could conclude with language very close to absolute certainty that they were not fired from the same barrel.

Subclass marks garner much attention from both examiners and critics, but there are sound reasons to believe that the phenomenon results in far fewer errors than those stemming from human and laboratory errors. Examiners and examiners-in-training often conduct research on new and existing manufacturing methods to check for subclass marking. If subclass marking is discovered, most often it is reported in the literature, and thus the community is constantly alerted to suspicious production methods and their specific applications. Oftentimes subclass marks betray certain properties well known to examiners, such as uniform spacing on a specimen. Then too, the greatest practical risk is with breechface marks, and here a qualified examiner always observes other markings such as firing pin impressions to ensure consistency. Further, validity tests that have been performed to date have often made use of sequentially manufactured parts. These parts conceivably could have imparted subclass marks onto bullets and cartridge cases and thus would have severely tested the examiners. Finally, and though not a technical matter per se, reasonable scenario-based probability analyses, or thought experiments, would show that it's quite unlikely that an examiner in a crime lab or in private practice would come across specimens in a single case that display subclass marking of a type that would catch an examiner flat-footed.

In this vein it should be noted, however, that just as in the forensic fingerprint world, a massive imaging database filled with thousands if not millions of images of fired cartridge cases from widely separated crime scenes presents the examiner with an unconventional and likely more risky situation. The probability logic stemming from a so-called cold hit in an imaging database, with no other evidence linking the specimens, and even when confirmed with traditional microscopic analysis, is unlike that stemming from a traditional examination in which evidence is submitted to the examiner after or during an investigation. The imaging machinery deliberately searches and selects for specimen pairs with significant microscopic correspondence, without regard for whether these marks originate from the same guns or from coincidental/subclass marking. Thus, special care should be exercised with cold hits from imaging databases. In particular, the examiner should check both the breechface and firing pin marks to further reduce the risk of error from subclass or coincidental marking.

Recent Developments

In the past decade continued progress has been made in the quality and sophistication of database imaging systems. The algorithms of these systems sift through thousands of images to produce a best-match-candidate list. For the most part, the images are of cartridge-case breechface marks and firing-pin

impressions, from cartridge cases recovered at crime scenes throughout the United States, and from test-fired cartridge cases from firearms submitted to crime laboratories. Many other countries also have such systems. If the candidate listing produces images that to an examiner appear likely to identify to physical cartridge cases that are part of an existing examination, then the examiner can often have the imaged specimen(s) delivered to her laboratory for examination under the comparison microscope. These systems have been improved over the years with imaging of greater resolution, often being three dimensional rather than just two dimensional. Clearly these systems allow links to be made between crime scenes that otherwise would go undiscovered.

Whereas the database imaging systems do not effect definitive matches between specimens, but rather score candidates, other machines have been developed on an experimental basis that are designed to draw definitive conclusions. These also use some type of imaging technology, such as lasers or shadow profilometry. But they then usually go a step further and analyze the data obtained, with the output being some kind of conclusion. These systems also tend to provide a small level of validation to conventional human examinations, insofar as the comparatively unbiased and objective machines are clearly able to distinguish between known matches or controls and known nonmatches. To date, however, their performance does not match that of trained human examiners. Then too, the machines are expensive and limited in their applications, so that for the near term, they are unlikely to replace human judgment for normal casework. As research continues, however, this may gradually change, at least for certain applications, wherein such machines may routinely complement and support human judgment.

Increasingly in recent years there have been legal and scientific challenges to the validity of firearm and toolmark identification. One response has been the aforementioned experimental machines. Another ongoing trend – though largely independent of the scientific challenges and led by scientists in the United Kingdom, Australia, and New Zealand – is the adoption of a Bayesian framework and the scaling of examiner conclusions, wherein the inherently subjective nature of the examination process remains. In this approach, as applied to firearms and toolmarks, the definitive match conclusion and definitive elimination conclusion are often discarded in favor of likelihood-ratio-based conclusions obtained from a verbal scale rather than expressed numerically in a report. What formerly in many countries was reported as an Identification is increasingly becoming a statement such as, “The examination observations very strongly support the proposition that this bullet was fired from the barrel of this gun, as opposed to the barrel of an unknown gun”, or similar language.” A rifling characteristic and caliber match, without sufficient correspondence in microscopic detail, has previously been reported in most countries as an Inconclusive. It is anticipated that this will increasingly becoming a statement such as, “The examination observations moderately support the proposition that this bullet was fired from this gun”, or similar language.” The statements are calibrated to the nature of the examination observations, their strength, and to the existing scientific research; absent is the all-or-nothing pattern characteristic of traditional conclusions.

Introduction

Firearms examiners are frequently called on to estimate the range from which a gunshot was fired. The distribution of gunshot residue (GSR) on the target surface can be used for this determination. GSR consists of the following materials: (1) unburned propellant particles; (2) partially burned propellant particles; (3) soot from the combustion of propellant; (4) nitrates and nitrites from combustion of propellant; (5) particles of primer residue (oxides of lead, antimony, and barium); and (6) particles of bullet or bullet jacket. The following terminology is frequently used to characterize ranges of fire based on the deposition of GSR:

- Distant shot: The shot was fired from such a distance that no GSR reached the target surface. Distant gunshot wounds are circular or elliptical defects surrounded by a marginal abrasion or contusion ring caused by the bullet stretching and tearing the skin. The contusion ring is frequently obscured by a gray ring of bullet 'wipe,' consisting of lubricant and gunpowder combustion products. Distant bullet holes in clothing, walls, and the like will lack the contusion ring but will usually show a ring of bullet 'wipe.' An elemental analysis of the residue surrounding the hole may be required to determine whether a hole in an item of clothing, a door, or a wall is in fact a bullet hole.
- Close-range shot: The shot was fired close enough to the target surface for some GSR to reach it. For handguns, close range typically means within 12–18 inch. (30–45 cm). However, this is very much dependent on the type of ammunition being fired and the condition of the weapon. For rifles and shotguns, close range typically means within several feet. The GSR deposited on the target surface consists primarily of unburned propellant particles, partially burned propellant particles, and soot. The unburned and partially burned propellant particles produce what is called 'stippling' or 'tattooing.' The heated particles may be fused to the surface of the target. The particles may be driven into exposed skin (hence the name 'tattooing'). As the distance between the gun muzzle and the target surface decreases, the GSR pattern becomes smaller and more concentrated, with increasing amounts of stippling and soot deposition. GSR patterns display a variety of patterns, such as irregular, circular, or petal.
- Near-contact shot: The shot was fired at a range of 1 inch. (2.5 cm) or less. At this range, there will be a concentrated GSR pattern. The muzzle flash (the incandescent gases issuing from the muzzle) will also interact with the target surface. Hair will be singed. Textile fibers may be singed or even melted and the textile structure will be disrupted. Woven textiles will split apart in an X-shaped pattern; knitted textiles will show a large circular or elliptical hole.
- Contact shot: The shot was fired with the muzzle in contact with the target surface. It is useful to distinguish loose-contact shots from hard-contact shots. A loose-contact shot results when the muzzle of the firearm just touches the target surface. GSR may be blown out along the target surface or between layers of clothing. A hard-contact shot results when the muzzle is pressed tightly against the target surface. GSR tends to follow the bullet into the target and not soil the target's surface. The heat of the muzzle flash can scorch or melt textile fibers, producing a so-called ironing effect. Hard-contact gunshot wounds over bony plates (e.g., the vault of the skull) can produce characteristic stellate defects. These are produced when the hot propellant gases create a pocket between the overlying soft tissue and the bone (depositing GSR on the surface of the bone). The soft tissue is pressed against the weapon's muzzle, producing a patterned contusion. If the gas pressure is high enough, the soft tissue can split open; blood and tissue may be blown back into the weapon's muzzle. The soft tissue in loose- and hard-contact gunshot wounds frequently displays the cherry red color of carboxyhemoglobin, which is produced by the reaction of hemoglobin with carbon monoxide in the propellant gases. In order to conduct a range-of-fire determination, the firearms examiner requires certain pieces of evidence or information. He/she should have the original GSR pattern, the weapon believed to have fired the pattern, ammunition from the same lot as that used to fire the original GSR pattern, and knowledge of the weather conditions prevailing at the time of the shooting. In the case of a GSR pattern on skin, a scaled black and white or color photograph of the pattern is usually used for comparison purposes. However, black and white photographs may be misleading as some of the discoloration of the skin in a powder pattern is the result of a vital reaction of the skin to the impact of hot propellant grains. Even a color photograph may be misleading. Skin blemishes may be mistaken for stippling or tattooing. Ideally, the firearms examiner should be present at the autopsy of a shooting victim, so that he/she can examine the GSR pattern himself. Infrared photography image processing may assist in visualizing the patterns.

GSR patterns on clothing may not be readily visible, particularly if they are on a dark fabric or obscured by blood. In such a case, several techniques can be used to visualize the GSR pattern. In the case of patterns obscured by blood, infrared photography can render the pattern visible; blood is virtually transparent to infrared radiation, whereas soot is a strong infrared absorber. Infrared imaging devices have also been successfully used to visualize GSR patterns. Chemical tests may also be used to visualize a GSR pattern on a dark-colored garment or one that is bloodstained. C acid

(2-naphthylamine-4,8-disulfonic acid) reacts with traces of nitrates and nitrites in GSR patterns to produce dark red spots. In the Griess test, nitrites in the GSR pattern react with the Griess reagent (sulfanilic acid and 2-naphthylamine or sulfanilamide and *N*-(1-naphthyl)ethylenediamine) to produce an azo dye by means of the familiar diazotization reaction. For the C acid and Griess tests, the GSR pattern is transferred to a piece of desensitized photographic paper that has been impregnated with the appropriate reagent. The garment is placed on a towel on a laboratory benchtop with the powder pattern uppermost; the impregnated photographic paper is placed with the gelatin-coated side down and covered with a towel. A hot iron is then pressed over the entire pattern to transfer the powder pattern to the photographic paper. Treatment of the fabric, with sodium hypochlorite for instance, may enhance some patterns on dark fabrics.

The sodium rhodizonate test is also used in range-of-fire determinations. Sodium rhodizonate reacts with lead primer residue to produce a blue lead rhodizonate complex. This blue complex can be converted into a scarlet complex by treatment with tartrate buffer (pH 2.8). For the sodium rhodizonate test, the pattern is transferred to a sheet of filter paper, which is then sprayed with the sodium rhodizonate reagent, followed by the tartrate buffer solution. Alternatively, the tartrate buffer solution may be saturated with sodium rhodizonate and this saturated solution used to develop the GSR pattern. The sodium rhodizonate test may be made specific for lead by spraying the scarlet pattern produced by the sodium rhodizonate/tartrate buffer combination with dilute hydrochloric acid to produce a blue-violet pattern. Barium ion produces a red complex with sodium rhodizonate; however, the color of this complex is not affected by changing the pH. Mercurous ion, ferrous ion, and thiosulfate ion give red or orange colors with sodium rhodizonate solution, but these colors fade when treated with dilute hydrochloric acid. Ammunition containing lead-free primers will, of course, not produce residue containing lead and the sodium rhodizonate test will not produce a color reaction with powder patterns fired with such ammunition. If the ammunition primer contains zinc peroxide, zincon can be used to develop a primer residue pattern.

Once the firearms examiner has visualized the powder pattern, he/she will test fire the suspect weapon into cloth targets set at different distance from the muzzle of the weapon until a GSR pattern is obtained that closely approximates the questioned pattern in size and density. Care must be taken to use ammunition from the same lot as that believed to have been used to fire the questioned powder pattern. For this reason, police investigators should collect as evidence any unfired ammunition in the possession of the suspect. Stippling and soot deposition on the test-fired patterns is readily apparent to the naked eye; however, primer residue patterns on the test-fired targets must be visualized by chemical treatment, using sodium rhodizonate or zincon, as appropriate.

The range from which a shotgun pellet pattern was fired can also be estimated. Although the rule of thumb that a shotgun pellet pattern will spread 1 inch. for every yard the shot mass travels down range may be used for rough estimates, careful range-of-fire determinations require that the firearms examiner has the original pellet pattern, the shotgun believed to have fired it, and shotshells from the same lot as that used to fire the

questioned pellet pattern. The examiner also needs information about the weather conditions: wind speed and direction obviously affect the size and density of the pellet pattern; ambient temperature also affects the size of the pellet pattern (presumably by changing the rate of combustion of the propellant in the shotshell). The firearms examiner will test-fire pellet patterns into paper or cloth targets from a number of different ranges. The examiner may visually compare the test-fired pellet patterns with the questioned pattern and continue his/her test-firings until he/she obtains a test-fired pellet pattern that appears to match the questioned pattern in overall size and density. This simple approach can yield surprisingly accurate results. In a blind study, ten pellet patterns were fired at randomly selected ranges between 6 and 41 ft (2–12.5 m). Visual comparison of these ten patterns with test-fired patterns resulted in range-of-fire estimates with an average absolute error of only 1.5 ft (45 cm) and an average relative error of 6.8%. Elemental analysis of GSR around the entrance has been used to estimate distance, the assumption being that a negative relationship in GSR density exists as distance from the epicenter of the hole increases. Regressions using 1–3 elements have been successful at shorter (20–80 cm) distances.

Various attempts have been made to introduce statistical methods such as regression analysis into the estimation of the range of fire from a pellet pattern. Statistical methods require some measure of the size of a pellet pattern. If D_H is the horizontal spread of the pellet pattern, D_V the corresponding vertical spread, and N the number of pellets, the following measures of the size of a shotgun pellet pattern can be defined:

$$\begin{aligned}\langle D \rangle &= \frac{(D_H + D_V)}{2} \\ D &= \sqrt{D_H D_V} \\ A &= D_H D_V \\ d &= \frac{N}{D_H D_V}\end{aligned}$$

If x_i and y_i are the Cartesian coordinates of the i th pellet hole in an arbitrary coordinate system, then

$$S = \sqrt{\sum_{i=1}^N [(x_i - \bar{x})^2 + (y_i - \bar{y})^2]}$$

where

$$\bar{x} = \sum_{i=1}^N \frac{x_i}{N}$$

and

$$\bar{y} = \sum_{i=1}^N \frac{y_i}{N}$$

Finally, if R is the radius of the smallest circle that will just enclose the pellet pattern, R can be measured using a clear plastic overlay marked off with a series of concentric circles. Studies have shown that D_H , D_V , $\langle D \rangle$, D , S , and R are generally linear functions of the range of fire, whereas A and d are not. The calculation of S is laborious and has little to recommend it for practical work.

Regression analysis is familiar to most scientists and a variety of statistical computer software packages are currently

available which permit the calculation of regression equations and more importantly the confidence limits for the estimated ranges of fire. The major problem with the application of regression analysis to the problem of range-of-fire estimation is the large number of test-fired patterns required to determine the regression equation for pellet pattern size versus range of fire. A minimum of 20 test-fired patterns would be required for useful results. A firearms examiner rarely has available this many shotshells of the same lot as that used to fire the questioned pellet pattern. Two alternative approaches have been proposed for the determination of the confidence limits of estimated ranges of fire. In the first, three or more shots are test fired at each of several ranges and the largest and smallest pellet pattern sizes are plotted graphically. The lower confidence limit is the range at which the size of the questioned pellet pattern corresponds to the size of the largest pellet pattern size, whereas the higher confidence limit is the range at which the size of the questioned pellet pattern corresponds to the size of the smallest pellet pattern size. This procedure requires no assumptions about how the shotgun pellets are distributed in the pellet pattern. On the other hand, it is virtually impossible to determine the confidence level of the confidence limits. Confidence limits based on an assumed normal distribution of pellets within the pattern have also been explored. However, experimental evidence indicates that the distribution of pellets within a pattern is unlikely to be Gaussian. For example, 00 buckshot patterns typically consist of a series of superimposed triangles (for a nine-pellet load, two nearly coincident triangles with the third rotated roughly 60° with respect to the first two). No. 2 shot patterns have been shown to have bimodal distributions.

An additional complication in the estimation of the range of fire from a shotgun pellet pattern is the phenomenon called the *billiard ball effect*. This term refers to the spreading of a shotgun pellet pattern caused by an intermediate target. When shotgun pellets exit a shotgun barrel, they initially travel as an elongated mass. If the pellet mass encounters an intermediate target, the leading pellets will be slowed down; the trailing pellets will overtake the leading pellets, colliding with them and thus causing them to fly off at eccentric angles. If the pellets go through the intermediate target to strike the final target, the resulting pellet pattern may be larger than would be produced at the same muzzle-to-final-target distance in the absence of the intermediate target. In other words, the pellet pattern in the final target may appear to have been fired from a greater distance than was actually the case. The larger (and hence, more massive) the pellets, the denser the intermediate target must be in order for it to produce a billiard ball effect. Metal or plastic window screen will produce a significant billiard ball effect with no. 2 bird-shot, but the effect of these materials on 00 buckshot is trivial. Human skin can act as an intermediate target; as a consequence, care should be taken in making estimates of ranges of fire from radiographic images. As the muzzle-to-intermediate-target distance increases, the billiard ball effect diminishes and eventually disappears altogether. As the pellets travel away from the muzzle, the pellets in the shot mass separate from one another; eventually each pellet is traveling on its own trajectory and the slowing of the leading pellets by the

intermediate target will not result in collisions between pellets. The firearms examiner may be alerted to the existence of an intermediate target by the presence of markings (e.g., from window screen) or trace evidence (e.g., paint or wood splinters) on the shotgun pellets.

This article is reproduced from the previous edition, volume 2, pp. 953–961, © 2000, Elsevier Ltd.

Gunshot residue consists of a variety of materials: particles of the projectile or the projectile's jacket, unburnt particles of smokeless powder, partially burnt particles of powder, combustion products, and particles of primer residue. These materials are projected from the muzzle of the weapon in a conical cloud. The particles are slowed down by air resistance, with the larger particles traveling greater distances. Gunshot residue may also escape from various openings in the firearm: from the space between the chamber and the barrel in revolvers, from the ejection ports of self-loading or automatic firearms and even from the trigger hole. Gunshot residue escaping in this way may be deposited on the hands of the shooter and on the hands of someone who is grappling for possession of the firearm at the instant of its discharge. In the field of forensic science, the detection of gunshot residue become important in two aspects of the investigation of a shooting incident: the determination of the range from which a shot was fired and as an aid in the identification of the shooter. The first involves the examination of powder patterns on the surfaces of targets, and the second involves the analysis of residues removed from the hands of a suspected shooter.

The gross appearance of a gunshot wound can provide some insight as to the range from which it was fired. Distant gunshot wounds are fired from a sufficient distance that no powder residue reaches the body surface; only the bullet reaches the target. The injury in this case typically consists of a circular or elliptical defect surrounded by a contusion ring (a ring of bruising caused by the bullet's stretching and tearing of the skin); the contusion ring may be overlain by a gray ring, a ring of material wiped from the surface of the bullet as it passed through the skin. Bullet wipe consists of powder residue, bullet lubricant, and traces of metal and metal oxides from the surface of the bullet. A close range gunshot wound is one that is inflicted from a sufficiently short range that powder residue reaches the body surface. A close range gunshot wound will have the same features as a distant shot plus deposition of tattooing (also called stippling) and soot (finely divided combustion products from the burning of propellant). Tattooing or stippling consists of particles of unburned and partially burned propellant that are driven into the skin surface or the surface of the shooting victim's clothing. As the range of fire shortens, the pattern of tattooing and soot deposition becomes both smaller and denser. At near-contact range (less than about 1 in (2.5 cm), the hot gases comprising the muzzle flash will singe the target surface, burning hair and natural textile fibers, and melting synthetic fibers. The muzzle flash can split woven fabrics along the warp and weft directions. Forensic pathologists distinguish between loose contact and tight contact gunshot wounds. Loose contact gunshot wounds may show gunshot residue blown along the body surface or between layers of clothing. In addition to singeing from the muzzle flash, loose contact gunshot wounds may show ironing, i.e.

a stiffening of fabric due to contact with a hot surface, caused by the weapon's muzzle. Tight contact wounds usually show no gunshot residue on the body surface. If a tight contact gunshot wound is inflicted over a bony plate such as the vault of the skull or the sternum, it may appear as a stellate (starlike) defect with a patterned contusion from the weapon's muzzle. In this case, the hot gases from the muzzle of the weapon, separate the soft tissue from the underlying bone. The resulting pocket of hot gases push the soft tissue against the weapon's muzzle; if gas pressure is high enough, the soft tissue may tear, allowing the gas to escape. Blood may be blown back on to the hand or arm of the shooter; blood and tissue may also be blown into the muzzle of the weapon.

The determination of the range of fire from a powder pattern requires four things: the original powder pattern; the weapon that produced the pattern; ammunition from the same lot as that used to produce the original pattern; and knowledge of the weather conditions. If the original powder pattern is on clothing, its preservation is straightforward. On the other hand, if the powder pattern is on the skin of a shooting victim, a scaled photograph should be taken using color film. Because skin blemishes (small moles, freckles, and the like) may be mistaken for tattooing or stippling – even in a color photograph – the examiner who will make the range of fire determination should be able to examine the powder pattern himself. From time to time recommendations for the excision of powder patterns from the bodies of deceased have appeared in the forensic science literature. The skin is sutured to a metal hoop and then carefully cut away from the body. The excised skin is then treated with a preservative such as formaldehyde. As an alternative, the excised tissue may be preserved by freezing. Although excision of the powder pattern may be necessary for laboratory analysis, the firearms examiner need to be aware that the actual removal of the powder pattern is fraught with problems. To begin with, the skin may be stretched or shrunk, altering the size of the powder pattern. At trial, the judge may exclude the admission of the powder pattern as evidence on the ground that the prejudicial effect of the admission of such evidence outweighs its probative value. Finally, relatives of the deceased may regard the excision of the powder pattern as a desecration of the victim's body.

A questioned powder pattern on clothing or other textile may require special treatment to render it visible, particularly if the fabric is dark colored or soaked with blood. The soot in a powder pattern strongly absorbs infrared radiation. Therefore, it may be possible to photograph a powder pattern on the surface of a dark garment using infrared film and special camera filters that exclude visible light. The hemoglobin in blood does not strongly absorb infrared radiation; therefore, infrared photography can be used to visualize powder patterns on bloodstained garments. Forensic light sources (e.g. Polilight®

or Omnichrome® 9000) have also proved useful for the visualization of powder patterns: partially burnt nitrocellulose particles fluoresce when illuminated with 415 nm light. Many forensic science laboratories use chemical methods to visualize powder patterns. First, the powder pattern is sprayed with a dilute solution of sodium rhodizonate, which reacts with the residues of lead primer compounds to form a blue lead rhodizonate complex; the color of the lead complex is changed from blue to red by spraying an aqueous tartrate buffer solution. The primer residue pattern is photographed before additional tests are carried out.

Users of the sodium rhodizonate test have noted several problems with it. An aqueous solution of sodium rhodizonate decomposes very rapidly; and the final blue color may be subject to unpredictable rapid fading. A study of the chemistry of the reaction of sodium rhodizonate with lead has also revealed that if the complexation reaction takes place at neutral pH rather than at pH 2.8 (the pH of the tartrate buffer), the formation of tetrahydroquinone will be favored over the formation of the scarlet lead-rhodizonate complex. Tartrate ion seem to participate directly in some way in the complexation reaction. To deal with these problems a modification of the sodium rhodizonate test has been proposed. In this new procedure, the powder residue is transferred to a sheet of filter paper. The filter paper is then sprayed first with tartrate buffer, then with a saturated aqueous sodium rhodizonate solution or a tartrate-buffered saturated sodium rhodizonate solution (which has a half-life at room temperature of about 10 h). When lead is present, the scarlet lead-rhodizonate complex is formed. The scarlet complex is decomposed by spraying the pattern with 5% aqueous hydrochloric acid until the blue color reaches maximum intensity. The hydrochloric acid is removed by drying the filter paper with a hair drier. The blue pattern will be indefinitely stable.

After the sodium rhodizonate test, the combustion products of smokeless powder are visualized with the Griess test. A sheet of unexposed photographic paper that has been treated with developer and fixer and carefully washed, is impregnated with Griess reagent. The questioned powder pattern is placed over the impregnated photographic paper in contact with the gelatin-coated surface and covered with a dampened towel. An electric clothes iron is used to iron the powder pattern on to the photographic paper where nitrites in the pattern react with the Griess reagent to produce a rose-colored azo dye through a diazo coupling reaction. The reaction of the powder pattern with Griess reagent can be enhanced by spraying the pattern with aqueous sodium hydroxide solution and heating it in a laboratory oven. Under alkaline conditions, nitrocellulose disproportionates to yield nitrite ions. The interpretation of the powder patterns visualized by the Griess reaction can be complicated by fabric dyes with similar colors to the Griess diazo reaction product: these dyes may leach out of fibers and bleed into the gelatin layer of the photographic paper.

Bloodstains can interfere with the Griess test. Traces of blood can be transferred to the test paper, either partially or completely, obscuring the color of the reaction product. The Maiti test was developed to avoid this masking problem. In the Maiti test, sheets of photographic paper are prepared by fixation in sodium thiosulfate solution, washed and then dried. Then the sheets are soaked in a solution of *p*-nitroaniline,

α -naphthol, and magnesium sulfate (0.25% of each in 1:1 aqueous alcohol). The impregnated paper is now dried and preserved for later use. When a powder pattern is to be visualized, a sheet of impregnated photographic paper is placed on the laboratory bench emulsion side up. The item of clothing bearing the powder pattern is then placed on top of the photographic paper with the surface bearing the powder pattern placed in contact with the emulsion layer of the photographic paper. A cloth moistened with 10% acetic acid is placed on top of the item of clothing and the whole stack is pressed with a hot iron to transfer powder particles to the photographic paper. Finally, the surface of the emulsion is swabbed with a 10% sodium hydroxide solution. The resulting powder pattern consists of blue flecks on a pale yellow background.

The weapon that produced the original powder pattern is test fired into pieces of white cotton sheeting at various ranges until a test-fired pattern with the same size and density as the original is produced. The original weapon must be used because its condition (e.g. degree of erosion of the bore) can affect the powder pattern. Likewise ammunition from the same lot as that used to produce the original powder pattern must also be used to obtain the test-fired patterns. Different lots of the same brand of ammunition may contain smokeless powder from different lots of propellant. Ammunition manufacturers often change lot numbers when a subplot of one component (projectile, casing, propellant, or primer) has been exhausted and the use of a new subplot of that component is begun. Propellants from different sublots may differ in the quantity of gunshot residue that they produce. To ensure that the firearms examiners have ammunition from the same lot as that used to fire the original powder pattern, investigators should seize as evidence any remaining boxes of ammunition in the suspect's possession.

Knowledge of the weather conditions at the time of the shooting is essential for the estimation of the range from which a powder pattern was fired. Wind and rain will disperse the gunshot residue. The ambient temperature may also affect the burning rate of the propellant and thus influence the appearance of the powder pattern.

The range from which a shotgun pellet pattern was fired can be estimated from the pattern of deposition of gunshot residue as discussed above or from the size and density of the pellet pattern. The making of such range estimates from pellet patterns is made complicated by the existence of different shotgun chokes. Many shotgun barrels are produced with constrictions at the muzzle whose purpose it is to concentrate the shot pattern. Common designations of the degree of choke of a shotgun barrel are the following: cylinder-bore (no choke), improved cylinder (slight choke), modified choke and full choke. The choke of a shotgun barrel can be determined by firing pellet patterns at a range of 40 yards (37 m): a full-choke barrel will place 65–75% of the pellets within a 30-inch (75 cm) circle; a modified choke barrel will place 45–65% within the circle; an improved cylinder barrel will place 35–45% within the circle; and the cylinder bore barrel will place 25–35% within the circle. The two barrels of a double-barreled shotgun frequently have different chokes. The choke of a shotgun can also be changed with barrel inserts or adjustable compensators. Obviously the choke of a shotgun affects the size and density of the pellet pattern it fires at any given

range. Several approaches have been used to estimate the range of fire from the size and density of a pellet pattern. Some firearms examiners have used the rule of thumb that a shotgun pellet pattern spreads about one inch (2.5 cm) for each yard (meter) that the shot string travels down range. Another approach is to test fire the weapon that fired the pellet pattern in question, at various ranges into paper or cardboard targets until a pellet pattern of the same size and shot density as that of the questioned pellet pattern is obtained. The test-fired patterns must be obtained using shotshells from the same lot as that used to fire the questioned pattern. Studies have shown that the size of shotgun pellet patterns produced by different lots of the same brand of ammunition are statistically different. Knowledge of the weather conditions at the time the questioned pattern was fired is also important. The ambient temperature has been shown to affect the spread of shotgun pellets. Attempts have also been made to apply regression analysis to the estimation of the range of fire from the size of a pellet pattern. However, the application of regression analysis to the estimation of the range of fire of a shotgun pellet pattern require a large number of test-fired pellet patterns (more than twenty if the confidence limits of the estimate are to be forensically useful). Rarely will sufficient shotshells from the same batch as that used to fire the questioned pattern be available to the firearms examiner for use in regression analysis.

Although many of the same procedures may be used both to visualize powder patterns and to detect gunshot residue on the hands of a suspected shooter, it must be strongly emphasized that the purposes of these two types of analysis are quite different. In the first case, the test results are used to estimate the range from which a gunshot was fired, and in the second case the test results are used to link a suspect with the discharge of a firearm. The first test for the presence of gunshot residue on the hands of a suspect was the dermal nitrate test (also called the paraffin test, the Gonzalez test, or the diphenylamine test) which was introduced in the 1930s. The test was developed by Tomas Gonzalez, chief of police of Mexico City and later Chief Medical Examiner of New York City. Gunshot residue was removed from the suspect's hand using a paraffin glove. A layer of melted paraffin was carefully 'painted' on to the hand and then while it was still soft the paraffin was reinforced with a layer of surgical gauze. Further layers of melted paraffin and gauze would be applied to produce a thick glove that could be handled without danger of disintegration. The glove would be allowed to cool and then it would be cut from the hand. Drops of diphenylamine reagent (typical concentration: 0.25 g diphenylamine and 0.25 g *N,N'*-diphenylbenzidine in 70 ml concentrated sulfuric acid) would be applied to the interior surface of the glove. Gunshot residue would be revealed by the presence of blue flecks whose blue color streamed off into the reagent solution. The diphenylamine reagent produces a blue color when it reacts with partially burnt particles of smokeless powder. The diphenylamine reagent also reacts with unburned and partially burned particles of smokeless powder. Because the dermal nitrate test is actually a test for oxidizing agents, a variety of materials may interfere with it: household bleaches (sodium and calcium hypochlorites); water treatment chemicals (calcium hypochlorite); fertilizers (ammonium nitrate); and explosives. Even the nitrates

in urine could produce a false positive test. Cosmetics and tobacco have also been found to interfere with the test. Because of these problems with the dermal nitrate test, an Interpol seminar unanimously recommended in 1963 that the dermal nitrate test no longer be used for either investigative or evidentiary purposes.

In 1959 Harrison and Gilroy published a chromogenic analysis scheme for the detection of primer residues. The suspect's hand were first swabbed with a small square of clean cotton cloth which had been dampened with 0.1 N hydrochloric acid. A drop of a 10% alcoholic solution of methyltriphenylarsonium iodide was placed on the cloth. An orange ring indicated the presence of antimony. After drying, the cloth was next tested with two drops of 5% aqueous sodium rhodizonate solution. A red color developing within the orange ring indicated the presence of barium or lead or both. The cloth swab was again dried and one or two drops of 1:20 hydrochloric acid were added to the red colored area. A blue color indicated the presence of lead; if the red color remained inside the blue-colored ring, barium was also present. The addition of the 1:20 hydrochloric acid was important because mercurous ion, ferrous ion, and thiosulfate ion give a red or orange color with sodium rhodizonate, but hydrochloric acid destroys the colored complexes with these ions. The detection limits for the three metal ions were determined by Harrison and Gilroy to be 4 µg of antimony in the presence of 1.5 mg of lead and 10 mg of barium, 10 µg of barium in the presence of 1.5 mg of lead (higher quantities of lead masking the color of the barium rhodizonate complex) and 2.5 µg of lead.

Instrumental methods of analysis have replaced the chromogenic methods discussed above in modern crime laboratories. Atomic absorption (AA) spectrophotometry has become the method of choice for many forensic science laboratories for the analysis of suspected gunshot residue. AA is much less expensive than neutron activation analysis (NAA), (see below) and it can detect lead, as well as antimony, and barium. The detection limits of AA for these elements are higher than those of NAA but are adequate for most gunshot residue samples. A typical AA spectrophotometer consists of a light source, a monochromator, a sample atomizer, a photomultiplier detector, and some type of read-out device. The light sources used in AA are hollow cathode lamps, which consist of glass envelopes with windows through which the radiation generated at the hollow cathode passes. The hollow cathode is a cylinder made of or coated with the element for whose analysis the lamp is to be used. The lamp is filled with a low pressure argon gas. When a high voltage (5000 V) is applied between the hollow cathode lamp's anode and cathode, the filled argon gas is ionized. The positively charged argon ions are accelerated toward the hollow cathode whose surface they bombard. Atoms are knocked from the surface of the hollow cathode in excited electronic states. The excited atoms emit the wavelengths of light characteristic of the element comprising or coating the hollow cathode. The light emitted by the hollow cathode lamp passes through a monochromator which isolates the wavelength of light which has been selected as the analytical wavelength. The emission profile of the analytical wavelength is much narrower than the absorption profile of gas phase atoms at the same wavelength. This is a necessary requirement for quantitative elemental analysis by AA because

Beer's Law is valid only when the absorptivity (or extinction coefficient) of the absorbing species is constant over the range of wavelengths passing through the sample.

The analytical wavelength next passes through the sample atomization region of the spectrophotometer where the analytical sample is vaporized and atomized. The analytical wavelength passes through the resulting cloud of gas phase atoms. Flame atomization has been a mainstay of the AA technique. The analytical sample (in the form of a liquid) is aspirated into a gas burner (burning acetylene in oxygen or nitrous oxide) where the heat of the flame first vaporizes it and then dissociates it into its component atoms. Flame AA is not appropriate for the analysis of gunshot residue. Lead, antimony, and barium, all form refractory oxides in the flame and so are unavailable to absorb the analytical wavelength. The use of carbon rod atomizers has also been explored; however, it was found that barium could not be determined by this method because it forms refractory barium carbide. Tantalum strip atomizers and graphite furnaces have been successfully used as atomizers for the analysis of gunshot residue.

AA is compatible with a wide variety of sampling techniques. Gunshot residue can be removed from the hands by swabbing or by dipping them into plastic bags containing a dilute acid solution. Tape lifts and film lifts can also be used to collect gunshot residue samples for AA analysis. The lifts must be ashed in an oxygen plasma; the primer residues are dissolved in an acid solution for AA analysis. Regardless of the method used to collect the gunshot residue, control samples of the materials used in the collection (e.g. acid solution, swab, lifting tape, or lifting film) must also be submitted for analysis to verify that these materials do not contain the elements of interest.

Scanning electron microscopy (SEM) has been used by some forensic science laboratories for the detection of gunshot residue. In the SEM, an electron beam is swept raster-fashion over the surface of the specimen. A detector collects electrons being produced by the surface of the specimens; an image is formed by converting the detector current into the intensity of a spot on a cathode ray tube whose scan is synchronized with the scan of the electron beam over the specimen surface. Two types of electrons are commonly detected: secondary electrons (electrons 'knocked' off the surface of the specimen by the electron beam) and backscattered electrons (electrons from the electron beam that are deflected backward by collisions with the electron clouds surrounding atoms in the specimen). Backscattered electron detectors have proved to be particularly useful in the analysis of primer residues because heavy atoms such as lead, antimony, and barium are very efficient backscatterers. Particles containing these elements appear brighter on the SEM image display. This allows the SEM operator to pick out the primer particles more quickly. Primer particles

take a number of forms; they may be single spheres or clusters of globules. The majority of primer residue particles are spheres ranging from 0.5 μm to 5.0 μm in diameter.

The morphology of primer particles is highly characteristic; however, the elemental makeup of the particles must also be examined. If the primer residue particles are bombarded with high-energy electrons, they can be made to produce X-rays. The high-energy electrons penetrate the electron shells of atoms at the surface of the primer residue particle. Collisions with inner shell electrons can lead to removal of an inner shell electron from the atom, producing a hole in the K shell. This hole can be filled by an outer electron falling into it; when it falls, the outer electron loses energy in the form of an X-ray photon. The emitted X-ray photon is detected by an energy-dispersive X-ray analyzer (hence the name SEM/EDX). The X-ray emission lines of antimony, barium, and lead are given in Table 1.

In 1994 the ASTM (American Society for Testing and Materials) Committee E-30 on Forensic Science adopted guidelines (Standard E 1588) for SEM/EDX analysis of gunshot residue, including guidelines for the interpretation of the results of the elemental analysis. The recommended operating parameters for the SEM/EDX system were: (1) that the SEM when operating in the backscattered mode, be capable of detecting potential gunshot residue particles down to a diameter of 0.5 μm ; (2) that the instrument be capable of producing a 3:1 signal-to-noise ratio for the lead $L\alpha$ emission line from a lead particle no larger than 1 μm in diameter; and (3) that the instrument be capable of resolving the $L\alpha_1$, $L\beta_1$, and $L\beta_2$ emission lines. To fulfill these requirements the SEM/EDX must be capable of operating at a 20 KeV accelerating potential or higher.

The following combinations of elements have been observed only in primer residue particles: lead, antimony and barium; and antimony and barium. Other combinations are consistent with primer residue but might derive from other sources: barium, calcium, silicon with a trace of sulfur; lead and antimony; lead and barium; lead; barium.

Samples for SEM analysis may be collected in a variety of ways. Both tape lifts and film lifts have been used. The lifts are sputter-coated with carbon to ensure electrical conductivity and prevent charging of the tape or film surfaces. Metal SEM sample stubs coated with adhesive can also be used. Carbon is used to sputter-coat the samples because its x-ray emissions are blocked by the beryllium window of the SEM's x-ray analyzer. Because observation of the morphology of the particles is essential to the identification of primer residue, sample collection methods (e.g. swabbing with dilute acid or dipping in dilute acid) in which the primer residue particles are dissolved, cannot be used.

Some forensic science laboratories have begun to use x-ray microfluorescence for the analysis of gunshot residue. In this technique a narrow beam of x-rays is focused on the sample.

Table 1 x-Ray emission lines (KeV)

No.	Element	$K\alpha_1$	$K\alpha_2$	$K\beta_1$	$L\alpha_1$	$L\alpha_2$	$L\beta_1$	$L\beta_2$	$L\gamma_1$
51	Sb	26.3591	26.1108	29.7256	3.60472	3.59532	3.84357	4.10078	4.34779
56	Ba	32.1936	31.8171	36.3782	4.46626	4.45090	4.82753	5.1565	5.5311
82	Pb	74.9694	72.8042	84.936	10.5515	10.4495	12.6137	12.6226	14.7644

The x-rays ionize some of the atoms in the sample by removing inner shell electrons; outer shell electrons fall into the resulting vacancies, emitting fluorescent x-rays as they do so. The emitted x-rays are then analyzed by an energy-dispersive x-ray spectrometer. Instruments such as the Kevex Omnicon energy dispersive x-ray microfluorescence spectrometer are capable of scanning a large area and generating maps of the intensities of the fluorescent x-rays. Consequently, x-ray microfluorescence has the capability not only of determining the presence of lead, antimony, and barium in primer residue but also of showing their distribution pattern on the target surface.

The use of neutron activation analysis (NAA) for the detection of primer residues was developed during the heyday of the exploitation of NAA in forensic science. In NAA, the sample is exposed to bombardment by thermal neutrons in the core of a nuclear reactor. Stable isotopes of lead, antimony, and barium (Table 2) capture neutrons and are converted into radioactive isotopes. After the sample is removed from the reactor, the induced radioactivity is measured with a γ -ray spectrometer. The γ -ray energies measured identify the radioactive isotopes present in the sample (Table 3) and the number of γ -rays indicate the number of radioactive nuclei present. Although NAA has a number of attributes that commend it for the detection of primer residues, such as very low detection limits and compatibility with a number of sampling methods, it also suffers from a number of flaws. The most obvious is the cost

associated with this method of analysis. Another is the procedure's inability to detect lead. Although the common stable isotopes of lead may be converted into radioactive isotopes by neutron bombardment, none of these isotopes emit γ -rays. Low-resolution γ -ray detectors have also posed problems. When such detectors are used, the most intense γ -ray emission of ^{139}Ba can be obscured by a γ -ray emission of ^{24}Na . Perspiration will produce very high levels of sodium in samples taken from the hands. Initially, the interference from sodium was removed by radiochemical separation. However, Krishnan has developed a NAA procedure using a series of irradiations followed by cool down periods to alleviate the interference from ^{24}Na . For example, the sample is irradiated at a neutron flux of 5×10^{12} neutrons $\text{cm}^{-2} \text{sec}^{-1}$ for 40 mins. The induced barium radioactivity is counted immediately. The sample is returned to the nuclear reactor for irradiation at the same flux for five hours. After a two-day cool down period the induced antimony radioactivity is counted. The long cool-down period permits most of the ^{24}Na radioactivity to disappear.

Samples for NAA analysis can be obtained in a variety of ways. The paraffin glove method used in the dermal nitrate test was the first to be used. Later it was deemed easier to remove the primer residues by dipping the hands into a plastic bag containing a dilute nitric acid solution or by swabbing the hands with cotton-tipped swabs dampened with a dilute acid solution. The swabbing method of sample collection is used in commercially packaged NAA gunshot residue collection kits. Swabbing is now the collection method of choice. Swabs can be collected from several areas on the firing and non-firing hands (e.g. web between thumb and forefinger, back of the hand, and palm of the hand). High levels of antimony and barium in the web area of the right hand of a suspect with low levels elsewhere would be consistent with the suspect having discharged a firearm. On the other hand, elevated levels of antimony and barium on the palm of one or both hands would be consistent with the suspect merely handling a firearm. Regardless of the method of sample collection chosen, the low detection limits of NAA require that negative control samples (reagent solutions, swabs and the like) also be submitted for analysis so that the absence of antimony and barium from the sampling media can be demonstrated. Early in the development of the swabbing technique, some samples of cotton swabs were found to have high levels of barium in their wooden shafts.

A 1992 survey of forensic science laboratories in the United States and in two Canadian provinces found that 44% of the respondent laboratories used AA by itself. About 26% of the laboratories used SEM/EDX by itself and 29% combined AA and SEM/EDX. Only 2% of the respondent laboratories were still using NAA for gunshot residue detection. The laboratories reported a wide range of threshold values for reporting a positive result: for Pb 0.1–2.0 $\mu\text{g ml}^{-1}$; for Ba 0.1–1.0 $\mu\text{g ml}^{-1}$; and for Sb 0.02–0.2 $\mu\text{g ml}^{-1}$.

Ammunition manufacturers have begun to introduce lead-free primers. Not only do these primers lack the lead azide or lead styphnate primary high explosives, they also do not contain antimony sulfide or barium nitrate. The primary high explosives used in lead-free primers include diazodinitrophenol and tetracene. Zinc peroxide or strontium nitrate may be added as oxidizers and fine titanium particles may also be

Table 2 Stable isotopes of barium and antimony

Isotope	% Natural abundance
^{134}Ba	2.42
^{135}Ba	6.59
^{136}Ba	7.81
^{137}Ba	11.32
^{138}Ba	71.66

found in the primer mixture. Elemental analysis of primer residues produced by lead-free primers, reveal particles containing zinc and titanium or particles containing strontium. Lead and antimony from the surface of lead-alloy bullets may also be incorporated in the primer residue particles. Firearms which have been previously used to fire ammunition having lead-based primers, have been found to produce residue particles containing up to four elements. Primer residues produced by lead-free primers have similar morphologies to those produced by conventional primers: spheres and clusters of spheres. The mechanism by which primer residue particles are formed is basically the same: the metals condense from a hot vapor. The SEM/EDX therefore remain a viable method for identifying primer residues. However, residues from fireworks and flares have been found to contain particles with a similar morphology to those produced by primers containing strontium.

A growing body of research has been focused on the analysis of the organic constituents of smokeless powder, which may also be detectable in gunshot residue. Smokeless powder consists of nitrocellulose to which a variety of compounds may have been added: the energetic plasticizers nitroglycerin and dinitrotoluene, stabilizers such as diphenylamine and ethyl centralite, and nonenergetic plasticizers such as dibutyl phthalate and triacetin. Gas chromatography-mass spectrometry (GC-MS) and high-performance liquid chromatography (HPLC) have both been applied to the detection of the organic additives in smokeless powders; however, micellar electrokinetic capillary electrophoresis (MECE) has shown the greatest promise as a method for the detection of organic compounds in gunshot residue. In conventional capillary electrophoresis ionic species are separated on the basis of their electrophoretic mobilities (which are dependent on such factors as the effective sizes of the ions, their electrical charges, and the viscosity of the medium in which the electrophoresis is taking place). If the wall of the capillary bears ionized groups (e.g. Si-OH in the case of fused silica capillaries) ions of opposite charge will be attracted to the wall of the capillary, leaving the solution in the capillary with a net electrical charge. Application of a voltage through the capillary results in a net flow of the solution through the capillary. This phenomenon is called electroendosmosis (EEO). In MECE an anionic detergent such as sodium docetyl sulfate (SDS) is added to a buffer solution; the detergent forms micelles, spherical aggregates in which the nonpolar tails of the detergent molecules project into the center of the aggregates and their electrically charged heads project out into the buffer solution. The anionic detergent micelles have a large net negative charge, which gives them a large anodic electrophoretic mobility. If the electrophoresis buffer has a large EEO flow toward the cathode (as most do) the capillary will contain a fast moving aqueous phase and a slow-moving micellar phase. Mixtures of organic compounds can be separated based on the compound's differential solubility in the micelles: compounds that are very soluble in the micelles migrate with the slow-moving micelles, whereas compounds that are more soluble in the buffer will migrate more rapidly. The eluted compounds are detected by their absorption of ultraviolet light. The advantage of MECE over GCMS is that MECE separations take place at room temperature so that temperature labile compounds (e.g. nitroglycerin) are less

likely to undergo decomposition. Because of its flow profile, MECE is capable of higher resolution than HPLC.

In some cases, criminal defendants claim that a negative test for the presence of gunshot residue on their hands show that they did not discharge a firearm. The interpretation of the results of tests for gunshot residues is not so simple. First of all, many firearms deposit little or no detectable residue on the shooter's hands. Surveys of firearm suicides in which hands-wabs were collected and submitted for gunshot residue have found gunshot residue detection rates varying from 62% to 38%. In the case of a living shooter, the gunshot residue may be removed by washing the hands; it may also be rubbed off the hands on to clothing. Because of the possibility that gunshot residue may be deliberately removed or inadvertently lost from a shooter's hands, other sources of gunshot residue should be considered. Gunshot residue may be deposited on the face and hair of the shooter or on his clothing. Gunshot residue deposited in these areas will generally be retained longer than gunshot residue on the hands. Nasal mucus has also been explored as a source of gunshot residue samples. The problem with these alternate sources of gunshot residue is that finding traces of gunshot residue on the face, in the hair, on clothing, or in nasal mucus of a criminal suspect only establishes that the suspect was near a firearm when it was discharged.

Glossary

Anthropometry Relating to measurements of the human body; Bertillonage was a classification system based on a number of these measurements.

Chiridium Hand or foot.

Dactyloscopy Comparison of fingerprints for purposes of identification.

Friction ridge skin Specialized skin found on the palmar and plantar surfaces; characterized by raised ridges which assist with traction and increase tactile stimulation.

LASER Light amplification by stimulated emission of radiation; a device that emits a single wavelength of light and is employed as a forensic light source.

Minutiae Characteristics or events along a ridge which are considered during the comparison of fingerprints; also referred to as Galton details.

Papillary ridges Orderly rows of peg-like structures emerging from the dermis.

Spectroscopic Referring to the interaction between matter and radiated energy.

Introduction

For over 100 years, fingerprints have provided a reliable and efficient means of identification, proving its value in criminal investigations. The biological principles of permanence and uniqueness along with the capability to be classified have made fingerprints a fundamental tool in forensic science. A reproduction of the arrangement of the ridges present on the fingers can be deposited on an object or surface when the finger comes into contact with it. Recognition of this tendency as far back as the late 1800s has led to continued research and development of fingerprint visualization, detection, and recovery techniques to further their potential use for identification. Despite the established application of fingerprint identification over the past century, fingerprint science has recently faced challenges within the legal system regarding the legitimacy of individualizations. The information presented here is by no means an exhaustive review of the research performed nor are the scientists involved in unfolding the biological basis and classification methods of friction ridge skin comparison and identification, but it is the authors' intent to present a concise and sequential development of the science of Dactyloscopy.

Early History (221 BC–AD 220)

The first known evidence of the recognition of friction ridge patterns has been linked back to Kejimikujik Lake, Nova Scotia, Canada where a tracing of the hand was found etched into slate rock. This is believed to be the first documented anthropological illustration depicting the friction ridges and flexion creases

of the hand. Impressions of the hands have also been found in Altamira, Spain and Lascaux, France and are estimated to be over 17 000 years old. Similar impressions have been found in clay as far back as 5000 years ago. In addition to these findings, fingerprints are known to have been used as a form of signature and identification on the seals of contracts in China as early as 206 BC. Fingerprints were not scientifically researched until many years later during the seventeenth century.

Recognition of Friction Ridge Skin (1684–1858)

The first scientist to recognize and comment on friction ridge formations was the English Botanist Nehemiah Grew in 1684. In his publication *Philosophical Transactions*, Grew described friction ridge skin in detail to include the papillary ridges, the patterns they form, and the pores they contain. Grew is recognized as the first scientist to document his findings on friction ridge skin. In 1686, Marcello Malpighi, an Italian anatomist, mentioned the patterns of friction ridge skin while studying the skin using the recently invented microscope. Malpighi gathered his observations and formally published on the function, form, and structure of friction ridge skin in an article entitled *Concerning the External Tactile Organs*. A layer of the skin, the Malpighian layer, was later named after him in honor of his contribution to Dactyloscopy.

For almost a century and a half after the work of Grew and Malpighi, little advancement was made in the science of friction ridge skin. Eventually, in 1823, Johan-Evangelist Purkinje classified nine principal configuration groups of fingerprints and assigned each a name. His work was the first published research to describe and attempt to classify fingerprint patterns,

however, Purkinje did not research the subject any further. Years later in 1853, while serving with the British Civil Service in Bengal, India, Sir William Herschel noticed a great number of natives were receiving pensions from the government by impersonation. While Herschel held the position of Magistrate and Collector at Hooghly, near Calcutta, he was in charge of the criminal courts, the prisons, the registration of deeds, and the payment of government pensions, all of which he controlled through the collection of finger and palm prints. This marks the first use of friction ridge skin as a signature by a European. Throughout his career, Herschel continued to collect fingerprints and study them as a hobby. Eventually, Herschel realized fingerprints remain unchanged over time and differ from person to person. Herschel wrote a letter in 1877, later to be called the 'Hooghly Letter', explaining his belief that fingerprints should be used as the new system of identification in prisons in England. At the time, however, he received no response. Herschel continued empirical studies of permanence by publishing prints he took of himself in 1859, 1877, and 1916, demonstrating their persistence, echoing a previous study published by Hermann Welcker in 1898.

Criminal Applications and as a Means of Identification (1880–1905)

Shortly after Herschel wrote the 'Hooghly Letter', Dr. Henry Faulds became interested in friction ridge skin after seeing ridge detail on pottery found on a Japanese beach while working there as a medical missionary from Scotland. In October 1880, he became the first ever to publish about friction ridge skin in a scientific journal. In his letter to the editor *On the Skin-Furrows of the Hand*, published in the journal *Nature*, Faulds discusses the value of friction ridge skin and its application in criminal investigations. Faulds provided two examples of how prints can be used to identify a person at a crime scene within the article. The first example involved a greasy print found on a drinking glass that helped Faulds discover who had been drinking distilled spirits in his lab and the second described sooty fingerprints left on a white wall which resulted in the exoneration of an accused individual. On 25 November 1880, Herschel responded to Faulds' letter stating that he had already been using fingerprints for 20 years, since he first took the prints of Rajyadhar Konai in an attempt to prevent denial of his signature on a business contract and then, later, by recording the fingerprints of natives to prevent impersonation offering the 'Hooghly letter' as proof. Years later, in 1917 Herschel would acknowledge the difference between his and Faulds' use of fingerprints during their debate in 1880, giving credit to Faulds as the first to suggest the use of fingerprints for the identification of criminals from impressions left at crime scenes.

Prior to publishing in *Nature*, Faulds had written a letter to Charles Darwin detailing his research and soliciting his aid in continued studies into the topic. Darwin's health at the time would not allow him to pursue the proposal but he forwarded the letter to his cousin, Francis Galton. Galton developed an interest in fingerprints at approximately the same time that Faulds and Herschel were researching the topic. Galton began correspondence with Herschel and eventually compiled his

research into the first textbook on fingerprints, published in 1892, titled *Finger Prints*. In this book, Galton established that fingerprints are never duplicated and the arrangement of the ridges persists throughout the life of an individual. Galton was also the first to name and describe friction ridge minutiae which in recognition of his work are often referred to as 'Galton details.'

Around the same time Galton was publishing his work, the first working fingerprint classification system was being designed in Argentina by Juan Vucetich. Vucetich provided a viable filing system which he referred to as 'icnofalangometria.' Vucetich is credited with creating and implementing the first classification system leading to earliest replacement of anthropometric methods for filing criminal records.

In 1892, Inspector Eduardo Alvarez, a former student under Vucetich, played a crucial role in the investigation of the Rojas murders, a case in which a bloody fingerprint found at the crime scene was matched to the right thumb of Francisca Rojas, ultimately leading to her confession of the crime. This case was the first homicide to be solved by fingerprint evidence and, soon after, Argentina became the first country to rely solely on fingerprints as a method of identification.

The next working classification system came in 1897. This system was developed by Sir Edward Henry, Inspector General of Police for the Lower Provinces in Bengal, India. Henry developed this system with the help of two Indian police officers, Azizul Haque and Chandra Bose, who created a method of separating fingerprint records into a large number of groupings that were based on Galton's fingerprint pattern types and specific characteristics in those patterns such as ridge counts in loop patterns and tracings in whorl patterns. Soon after its development, the Henry system was introduced in Britain and for long was the most widely used classification system in the world eventually being replaced by the computerized systems in use today.

Prior to implementation of the Henry system, Anthropometry was the practical identification and classification method in use. Introduced by Alphonse Bertillon, Anthropometry, also referred to as Bertillonage, was based on 11 body measurements meticulously taken using calipers. Bertillon was a clerk at the Prefecture of Police in Paris, France and his system was originally put into use in 1882. Anthropometry was replaced by the Henry System in most countries by the early 1900s, however, its use continued in France until Bertillon's death in 1914.

In 1898, Sir Henry made an identification in a criminal case in Bengal, India in which the fingerprint evidence was used to secure a conviction for the first time and in 1900, recognizing the superiority of fingerprints as a means of identification. As a result, the Belper committee in England established that all criminal identification records would be classified by the Henry system. Ironically, in 1902, Alphonse Bertillon was responsible for the first use of fingerprints in Europe to solve a murder in Paris, France.

Shortly after the Henry System was put into use in Europe, fingerprint science was introduced to the United States by Detective John K. Ferrier in 1904 at the St Louis World's Fair. Det. Ferrier of New Scotland Yard was sent to guard the Crown's Jewels of the British Empire, which were on loan for exhibition. During the fair, New Scotland Yard set up an exhibition in which Ferrier demonstrated the use of fingerprints as

a method of identification and how they were being used in England. It was here that the science of fingerprints was taught to the first group of Americans, eventually leading to the incorporation of the Henry system in prisons throughout the country and the utilization of fingerprint evidence in criminal investigations. Just a year later, in 1905, the Deptford murder trial in England became the first case in which fingerprint evidence was used to secure a conviction within the English court system.

Developments in Comparison and Identification (1914–73)

Inevitably, the science of fingerprints continued to progress. In 1914, Edmond Locard, a former student of Alphonse Bertillon and the Director of the Laboratory of Police at Lyons, France, further promoted the use of fingerprints as powerful forensic evidence and he also introduced the theory of poroscopy. Locard explained how the study of pores and their locations on the ridges could be used to supplement fingerprint comparisons. In 1915, the International Association for Identification (IAI) was established and would grow to become the primary professional organization and governing body for practitioners of fingerprint science. A significant event occurred in 1924 when images of two fingerprints from different individuals exhibiting 16 points in agreement surfaced at New Scotland Yard. The images were originally published in a 1912 paper by Bertillon. Presented with the chance that the fingerprints from two different individuals could be so similar it was decided that the 12-point standard was not sufficient and 16 points became the new standard. Since that decision, examination of the prints in their original publication revealed that the images received by New Scotland Yard had been doctored. In 1953, a meeting was held between the then Deputy Director of Public Prosecutions, officials from the Home Office and officers from several police forces, for the purpose of agreeing on a common standard in fingerprint identifications. As a result, the National Fingerprint Standard was created, which required 16 separate similar ridge characteristics. Also in 1924, under the direction of J. Edgar Hoover, the Federal Bureau of Investigation (FBI) developed its Identification Division bringing together the International Chiefs of Police fingerprint records and the records housed at the Federal Penitentiary at Ft. Leavenworth, Kansas – a compilation that would become the Master Criminal File housed by the FBI.

One of the first cases of fingerprint fabrication occurred in 1943. On July 8, Harry Oakes was found murdered in his mansion in Nassau, Bahamas. Alfred de Marigny, Oakes' son-in-law, was accused of the crime. A fingerprint recovered at the scene and identified as de Marigny's was the major piece of evidence against him at trial. Police claimed that the print been developed on a Chinese screen in Oakes's bedroom where the body was found. Following a trial which lasted several weeks, he was eventually acquitted, after it was discovered that the print said to have been lifted from the screen had actually been lifted from a water glass that de Marigny had used during questioning by police and that the detectives had fabricated the evidence against him. Heightened awareness of the consequence of fingerprint identification was also evident outside of

the realm of investigators and scientists with criminals such as Jack Klutas and Donald Darling Roguerre carving into their fingers to mutilate the patterns thus precluding identification. John Dillinger went as far as applying corrosive acid to what he must have learned were 'key areas' – the deltas and cores – in order to destroy his fingerprints. Possibly the most infamous case of mutilation was Roscoe Pitts. With the assistance of a doctor, Pitts cut strips from the sides off his torso and removed as much skin as possible from his fingers. He then bound his hands to the skin strips for 3 weeks after which the edges of the torso skin strips were severed and the torso skin, which is absent of friction ridge detail, became grafted to the fingertips. Pitts was later identified from friction skin impressions of the second joints of the fingers.

Throughout the 1930s and 1940s, interest in dermatoglyphics grew within the universities as well. Furthering studies endeavored by Harris H. Wilder and Inez Whipple at Smith College in Massachusetts, and Harold Cummins, from Tulane University in Louisiana, conducted research on volar pad development. In 1952, a colleague of Cummins at Tulane University, Alfred Hale, published further research on volar skin development in the human fetus. These researches are discussed in further detail later in this article. In 1962, Salil K. Chatterjee described the use of the ridge edges and shapes and how they could be used to supplement fingerprint comparisons – which he termed edgeoscopy. Edgeoscopy along with poroscopy, described previously, would become what we refer to today as third level details.

Shortly after Chatterjee introduced edgeoscopy, Andre Moenssens published the books *Fingerprints & the Law* and *Fingerprint Techniques*, in 1969 and 1971 respectively, which became authoritative textbooks in the training and teaching of fingerprint science for many decades. In 1973, the IAI passed a resolution stating that there is no need to require a predetermined minimum number of characteristics to make an identification. This assertion would become fundamental in the shift toward ridgeology – a term introduced in 1991 by David Ashbaugh of the Royal Canadian Mounted Police (RCMP) in his paper *Ridgeology*. After the publication of his book *Quantitative-Qualitative Friction Ridge Analysis* in 1996, ridgeology or the study of ridges, quickly became the philosophy and approach for latent print comparisons. Till today, this is the prevailing philosophy behind fingerprint comparison.

Recent (1990–Present)

At the International Symposium of Fingerprint Detection and Identification in June 1995, the Ne'Urim Israeli Declaration was presented stating that 'No scientific basis exists for requiring that a pre-determined minimum number of friction ridge features must be present in two impressions in order to establish a positive identification.' This declaration was unanimously accepted by all present at the time, and later, signed by 28 persons from the following 11 countries: Australia, Canada, France, Holland, Hungary, Israel, New Zealand, Sweden, Switzerland, United Kingdom, and United States of America.

Two recent cases which have brought attention and challenges to the question of the reliability of fingerprint science are the Shirley McKie trial and the Madrid-train bombing

incident. In 1997, Shirley McKie, a detective with a Scotland police department, was identified by several Scottish Criminal Record Office (SCRO) Latent Print Examiners as having been present and entered upon a crime scene she claimed to have never entered. External experts reviewing the case believed the identifications were erroneous while the local experts, and others associated with the case, maintained that the identifications were accurate. Debate and controversy persisted for over a decade, with neither side shifting on their position. This precipitated a major Public Judicial Inquiry and on 14 December 2011 the report put the controversy to rest. The report sided with the external experts stating that both McKie's and the victim's fingerprints had been misidentified by the examiners involved. The report concluded that the identifications were a result of human error and that no impropriety had been committed by the SCRO examiners.

Another highly publicized error in fingerprint examination occurred in 2004 during the Madrid-train bombing in which the FBI erroneously identified a latent fingerprint from the crime scene to Brandon Mayfield, an American living in Portland, Oregon at the time of the incident. The case incited a tremendous amount of negative publicity for the fingerprint community and is used to challenge the soundness of fingerprint identifications in courts today.

The National Research Council (NRC) formed a committee through the National Academy of Sciences (NAS) to identify the needs of the forensic science community in the United States. The 2009 report emphasized the need for establishing an error rate and measuring the discriminability of features in latent print comparison work. It also addressed the lack of standardized training and procedures across agencies and practitioners in the fingerprint field. The national attention the report has received has stimulated the fingerprint community to critically evaluate the foundation of their science, fostering additional research in the field.

In 2010, the IAI passed a significant resolution (Resolution 2010-18) which allows the use of mathematically based models to assess the associative value of latent print evidence to provide a numerical basis for supporting an examiner's opinion. This resolution was monumental because prior to it, latent print examiners were not permitted to offer qualifying statements regarding the likelihood or probability of an identification. Interest in statistical models began as early as the probative value of fingerprints as a means of identification was realized. Historically, scientists and mathematicians such as Galton, Balthazard, Roxburgh, Amy, and Osterburg have all attempted to describe a probabilistic estimate of fingerprint individuality. Most recently, computer assisted models and statistical tools to provide likelihood ratios in fingerprint comparisons have been developed by Champod, Egli, and Neumann. The continued development of these models will offer the fingerprint community further support for their conclusions.

Early Scientific Foundation

As major advances were being made on the classification and comparison front of fingerprint science, study of the biological aspects of ridge development continued as well. Expanding on the external examinations of friction ridge skin described thus

far, Arthur Kollmann was the first to publish, in 1883, concerning the embryological development of ridges and went on to describe the presence and location of the volar pads on the hands and feet. It wasn't until 1897 that Harris H. Wilder put forward that the centers of disturbances – the core of the patterns – corresponded with the location of the volar pads as opposed to earlier propositions basing the location of the pads on topographical observations which often confused the pads with muscle structure. Wilder also suggested an association between the location of the volar pads and the epidermic ridges that developed upon them. As a fellow professor in the Department of Zoology at Smith College in Massachusetts, Inez Whipple came to share his interest in dermatoglyphics and in 1904 published a landmark treatise describing the arrangement of the volar pads on the mammalian chirodium and their influence on the formation of ridges and patterns upon these elevated surfaces. Wilder also collaborated with American Police Commissioner Bert Wentworth and in 1918 they published research on the uniqueness and persistence of incipient ridges and pores. Our current understanding of the formation and development of the papillary ridges has built upon the pioneering work of these early researchers.

In 1946, Harold Cummins and Charles Midlo published the authoritative work entitled *Finger Prints, Palms, and Soles* (1946), which included many of Cummins' earlier papers and the body of knowledge established by their forerunners on the subject of dactyloscopy. Cummins described in detail the development of the volar pads on fetuses and concluded that the onset of friction ridge development coincides with the regression of the volar pads and that the stage of regression along with the location, size, and shape of the pads influences the overall pattern configuration. Another major advancement in establishing the scientific premises for the uniqueness and persistence of friction ridge skin was the research presented by Alfred Hale describing differential growth. In summary, development of the friction ridges of the palmar surfaces begins around 13–16 weeks of gestation, which corresponds with volar pad regression. Differential growth explains how stresses resultant from differences in growth rate of the ridge units influences their arrangement into lines. Although, the overall pattern of friction ridge skin is influenced by heredity, the minutiae ensue from both localized surface tensions across the pads as ridges proliferate and pads regress, as well as, from environmental influences within the womb resulting in the randomized formation of ridge characteristics on which fingerprint identification is based.

Further Scientific Research

Research into both the morphological and embryological development of friction ridge skin has expanded the foundation laid previously. In 1976, Michio Okajima presented his research on incipient ridges and described the comparable double-row arrangement of the papillae under these smaller ridges to the double-row arrangement under normal ridges. Okajima's observations suggested that incipient ridges are primary ridges that were not completely matured at the cessation of ridge proliferation during differential growth. In 1984, Brigitte Lacroix et al. published the paper *Early Human Hand Morphology: An Estimation of Fetal Age* in which the authors

The Science of Fingerprints Historical Timeline

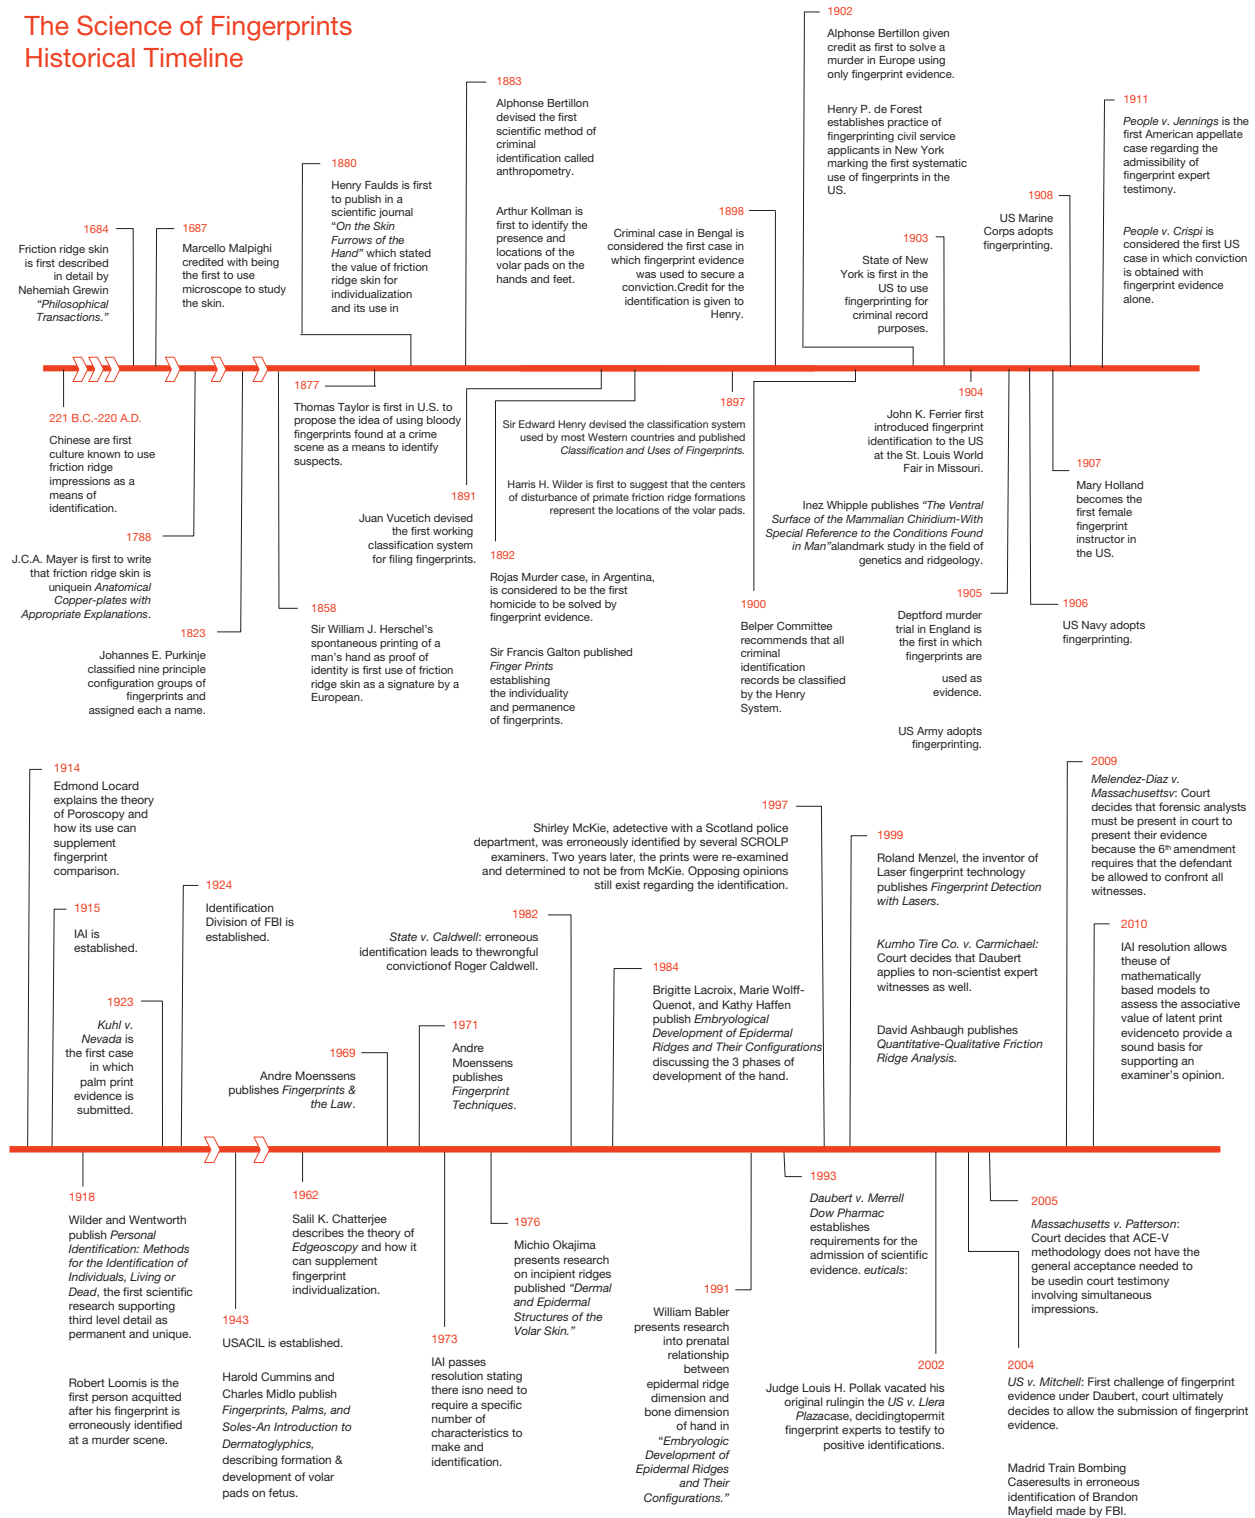

Figure 1 The science of fingerprints: historical timeline.

used scanning electron microscopy (SEM) to examine the development of pads and ridges on the hand. Their analysis confirmed original observations made by Katherine Bonnevie that development of the volar pads precedes the proliferation of ridges and also corroborated with the histological studies of Alfred Hale demonstrating the appearance of ridges as early as 13 weeks of gestation. Most recently (1991), William Babler has shown that the pattern formed by ridges is not only dependent on the shape and size of the volar pads, the timing of volar pad regression, and ridge proliferation but also prenatal bone dimension influences ridge configuration.

Fingerprint Detection and Enhancement

Visualization and, often, preservation of fingerprints is fundamental in their exploitation as a means of identifying individuals in contact with an object or crime scene. A plethora of methods are available for the enhancement of latent impressions on different surfaces each targeting different compounds – inorganics, amino acids, lipids and fats, moisture, etc. – in latent print residue. Traditional methods include powder dusting for nonporous surfaces, iodine fuming as a nondestructive method for porous surfaces, and physical developer for porous surfaces which may have been previously wetted. A major advancement in the development of latent impressions on porous surfaces came with the introduction of ninhydrin by the Swedish scientists Oden and von Hofsten in 1954. Ninhydrin, which forms a purple product upon reaction with amino acids, offered a non-fleeting method (as opposed to iodine fuming) for developing prints on papers and other porous surfaces. Analogous methods have since been developed which offer greater sensitivity and contrast by employing forensic light sources such as LASERS to visualize the developed prints. These include 1,8-diazafluoren-9-one (DFO) developed by Tony Pounds (1990) and 1,2-indanedione synthesized by R.S. Ramatowski (1997).

In 1978, the Criminal Identification Division of the Japanese National Police Agency took notice of cyanoacrylate, or superglue fuming and its ability to develop and preserve latent print residue on nonporous surfaces, a method that remains the work horse of most forensic laboratories today. Superglue fuming techniques work through the polymerization of cyanoacrylate esters with the eccrine and sebaceous components in fingerprint residue forming a readily visible white polymer in the areas where friction ridge skin came into contact with the surface. Almost simultaneously, Roland Menzel, Brian Dalrymple, and J.M. Duff were considering LASERS as a means of detecting latent impressions. Photoluminescence was first exploited as a latent fingerprint visualization technique in 1976 when the Canadian researchers took notice of the inherent luminescence in fingerprint residue and employed an argon laser to induce the substance to luminesce. By 1980, Menzel had implemented the process of dye staining non-porous evidence with Rhodamine-6-G after superglue fuming as a means of making the fingerprint residue luminesce more intensely and to overcome background fluorescence and

permit for optical filtering. Other detection techniques which expanded detection of latent impressions to more challenging surfaces and items exposed to varying environmental conditions have been introduced by the Home Office in Great Britain and include physical developer for the enhancement of impressions on previously wet items, vacuum metal deposition for developing prints on polyethylene bags and radioactive labeling for developing prints on adhesive tapes. Most recently, methods employing spectroscopic techniques utilizing visible and infrared absorption and reflectance are being investigated as rapid and non-destructive methods to visualize latent impressions on a variety of surfaces. The arsenal from which fingerprint examiners can draw to detect, develop, and capture latent impressions will continue to grow as research continues.

Introduction

Because of documentary shows, such as *Forensic Files*, and more fictionalized accounts, such as the *CSI* series, forensic science is a permanent part of the modern *zeitgeist*. These popular portrayals of forensic science are glossy, pretty, and dramatic – a far cry from the work actually done by forensic professionals. That popular perception obscures not only the professional reality of forensic science but also what it takes to become a forensic scientist, namely, a strong science education. With the increased recognition that forensic science needs to emphasize its scientific foundations, both from within the profession and from external critics, comes the realization that forensic science is a separate discipline, in its own right, and not ‘merely applied’ chemistry, biology, or other sciences. Popular interest flooded the existing forensic science programs, particularly with the high profile cases of the early 1990s, and the corresponding growth in the number of educational programs offering forensic science degrees contributed to the need for accreditation of such programs. Accreditation provides assurance for students on what to expect in a program and for employers of what the graduate should be able to do. The 2009 report from the National Academy of Sciences recommended increasing emphasis on graduate education in forensic science and, with

that, additional research to improve the reliability of the science used in investigations, laboratories, and courtrooms.

The first forensic science educational program in the United States was created in 1946 at Michigan State University; today, there are hundreds of programs with the word ‘forensic’ in their title (Figure 1). The profession of forensic science requires a solid grounding in the natural sciences, an understanding of statistics and interpretation, an appreciation for management skills, and the perspective of the role of forensic science in the criminal justice system.

With the increased recognition of forensic science as a separate discipline, additional calls from the community demanded improvement in the quality of forensic science education. Although accreditation and standardization of forensic science programs was not a new message, a confluence of effort, resources, and people was needed to act on the community’s desires.

What Is Accreditation?

In many countries, the national or local governments assume varying degrees of control over education, but generally educational institutions operate with expanded independence and

Figure 1 The growth in the number of forensic science programs has been particularly rapid in the last few years, probably in response to the increase in popular television shows highlighting forensic science. Reproduced from Peterson J and DeForest P (1977) The status of forensic science degree programs in the United States. *Journal of Forensic Sciences* 22(1): 17–33; Jackson G (2009) The status of forensic science degree programs in the United States. *Forensic Science Policy and Management* 1(1): 2–9.

autonomy. Academic institutions and programs, therefore, rely on accreditation to ensure that they are meeting acceptable, established standards of educational quality. Accreditation, generally, is a voluntary peer-review process offered by non governmental entities. While accreditation does not lead to rankings of institutions or programs, it does provide significant stakeholders (e.g., employers, graduate, or professional schools, and certification or licensure boards) with a measure of assurance of what the graduate should have learned. Two types of academic accreditation exist. Institutional accreditation reviews a college or university as a whole. Specialized accreditors, as is discussed below, assess only specific educational programs, such as forensic science programs.

Accreditation of Educational Programs in North America

A technical working group on education and training in forensic science (TWGED) was convened by the National Institute of Justice and a report was issued. The report covered four areas: What prospective students could expect from a career in forensic science, undergraduate curricula, graduate curricula, and guidelines for continuing professional development. This report provided the first coherent consensus on what a forensic science degree should contain. The American Academy of Forensic Sciences (AAFS) recognized the importance of this document and created an *ad hoc* committee in 2002 to convert the TWGED guidelines into enforceable standards; the following year, the committee became the Forensic Science Educational

Program Accreditation Commission (FEPAC) and a permanent, although independent, part of the AAFS. The mission of FEPAC is to maintain and to enhance the quality of forensic science education through a formal evaluation and recognition of college-level academic programs. The primary function of the Commission is to develop and to maintain standards and to administer an accreditation program that recognizes and distinguishes high-quality undergraduate and graduate forensic science programs. Five educational programs volunteered to part of a pilot accreditation project in 2004. In 2008, FEPAC was recognized by the Association of Specialized and Professional Accreditors (ASPA). As of February, 2011, 35 programs are accredited by FEPAC, 18 bachelors and 17 masters.

FEPAC accredits forensic science educational programs that lead to a bachelor's or graduate degree in forensic science or in a natural science with a forensic science concentration. The program must be housed in a regionally accredited institution of higher learning. All programs must adhere to a set of basic standards regarding planning and evaluation, institutional support, student support services, administrative practices, and student complaints. The director and the faculty must be able to fully support the programs mission and goals. Programs must have interaction with operational forensic laboratories and are responsible for keeping records of student achievement. An application is submitted to FEPAC and is reviewed for suitability. If appropriate, the applicant university then prepares and submits a self-study, which details the program's resources, faculty, courses, and processes. A site evaluation team, consisting of one academic and one practitioner, visits the program to assess the suitability of the facilities,

interview the faculty and students, and review documentation. The evaluation provides the 11 FEPAC Commissioners (five practitioners, five academics, and one public member) with the basis for reviewing and voting on the program's accreditation. The programs are notified of the results soon after the vote, typically held at the annual AAFS meeting.

Undergraduate forensic science programs have to ensure that each student obtains a fundamental education in the natural sciences, build upon this foundation with increasingly advanced science courses, and develop an appreciation for the articulation between science, forensic science, and its application. Specific courses, some with laboratory components, must be taken in biology, physics, chemistry, and mathematics. An additional compliment of specialized science courses, along with additional forensic science coursework, is required. Advanced courses are also required to deepen a student's understanding and knowledge of science and forensic science.

Graduate programs vary in their structures and the FEPAC graduate standards acknowledge this fact. Unlike the undergraduate standards – which are fairly proscriptive and structured on which courses and how many credits – the graduate standards are more flexible and allow programs to specialize (e.g., forensic molecular biology). A graduate seminar is required, as is a written thesis or its equivalent that is subjected to peer review. Additionally, original research reviewed by a committee of at least three individuals – at least one of whom must be a forensic practitioner – is required; the research must be presented publicly. With the NAS report, among other criticisms of and suggestions for forensic science, research is a key aspect of improving and shaping forensic science as a scientific discipline.

According to a 2010 NAS report on doctoral programs in the United States, no forensic science doctoral programs, either professional (like a MD or a DDS) or research based (like a PhD), currently exist in the United States or Canada; such programs do, however, exist outside the United States in Australia, the European Union, and the United Kingdom. PhD degrees with an emphasis in forensic science research are offered in the United States and Canada but these degrees are housed within a nonforensic science department, like chemistry or biology. The complexity and richness of forensic science as a research discipline means that PhD or professional doctorates will eventually become more common and a part of the US educational landscape. The 2009 National Academy of Sciences report recommends additional funding for forensic science graduate programs and research to improve the reliability and effectiveness of forensic science.

Accreditation of Educational Programs in the United Kingdom

In the United Kingdom, the Forensic Science Society accredits academic programs which deliver forensic science undergraduate and postgraduate programs (or 'courses,' as they are referred to in the United Kingdom). The accreditation process is open to UK programs and those outside the country. The accreditation accords with the component standards that the Forensic Science Society espouses for a quality forensic science educational program. To date, 17 institutions in the United

Kingdom have some level of accreditation from the Forensic Science Society.

The Forensic Science Society's accreditation process takes a case-based perspective and emphasizes the three essential elements of a forensic case: the investigation of the crime scene, the analysis of the evidence in the laboratory, and the interpretation, evaluation, and presentation of the crime scene and/or laboratory results. The accreditation process reviews all three areas and how they are covered in general courses (for the Bachelors of Science degree); depending on the focus of the courses, the program may be accredited for only two areas, for example, if the program offers a degree in forensic biology, only the laboratory and interpretation components will be considered. The Chair of the Standards and the Assessment Team make this decision but regardless all courses must meet the standards outlined for interpretation, evaluation, and presentation of evidence.

The applicant university prepares and submits an overview which is reviewed by the Standards and Assessment Team; if the program passes this first review, it then prepares and submits an in-depth matrix for each course showing how the component standards are met by the course material. The application and documentation are evaluated by an assessment panel consisting of a faculty (who acts as the Chair), one other academic, and one practitioner. A site visit to the university may be required. The program is informed of the panel's decision within 2–3 weeks of the review.

Education and research in the forensic sciences in the next decade will require strong science skills, mathematics, statistical ability, and a creative mindset willing to ask fundamental questions. Accreditation of forensic science programs provides an assurance of quality, relevancy, and stringency to provide the knowledge, skills, and abilities the forensic profession will need to meet its challenges.

Certification and Licensing

RJ Garrett, Denver, NC, USA

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Accreditation The evaluation of a program by an external board attesting to its quality, effectiveness, and fair administration.

Certification A credential issued by an examining board attesting to the individuals, foundational knowledge and skill regarding a specific discipline.

Competence A measure of acquired knowledge and skill necessary to reliably conduct a task.

Licensing A means used by governments to ensure practitioners have met a standard of education and skill necessary to safely and reliably practice a profession.

As members of an organized society, it is necessary from time to time to provide for the collective and individual interests of citizens by offering services that can affect their health, general welfare, property rights, and possibly their liberty. Because of the severity and potentially negative impact these services may impose on fellow citizens, control must be exercised to ensure that services are rendered in accordance with the best professional practices and with respect to the rights of the citizenry and the laws by which they are governed. In the realm of forensic science, that insurance comes in the form of accreditation, licensing, and certification.

Accreditation is the means by which service providers, agencies, and laboratories are evaluated for the quality and effectiveness of their operation. While accreditation assesses the structure, that is, the program model for credentialing, the substance is guided through licensing and certification.

Licensing has long been a means by which a legally constituted authority (government) endorses or allows a particular activity. These activities usually involve an element of public safety or welfare hence the necessity for regulation. A licensee is usually required to have completed a level of professional education and will usually undergo some form of testing or evaluation that demonstrates general competence in a given profession (e.g., doctors, lawyers, plumbers, electricians).

Licensing is not a common requirement for forensic practitioners. Many disciplines that are used forensically are not primarily forensic sciences. Two professions commonly utilized forensically that require licensing are medicine and engineering. A medical examiner, depending on jurisdiction, may not be required to be certified in forensic pathology but does need to be licensed as a physician in the state where he/she practices.

Certification is a more specific endorsement than licensing and dealing with specialties or disciplines within a profession. Certifications are usually issued by professional bodies that have organized to promote ethical and proficient conduct among practitioners. Certification is customarily achieved through successful completion of a course of study accompanied by practical experience and, as with licensing, some form of testing or evaluation.

Certification is sometimes confused with measuring competency. Competency to practice a task means that the practitioner has a basic understanding of the underlying principles of

the discipline and can apply the method or process by which the task can be accomplished. Certification, on the other hand, not only assures competency but also infers a quality value of the practice. One anticipates that a certified practitioner possesses a higher level of understanding of the discipline and its roots and has the knowledge and skills to achieve results that may be beyond the capability of their noncertified counterparts.

In some jurisdictions, certification has become a sort of de facto licensing where legislatures have required forensic practitioners to be certified in order to testify as an expert. Some employers now require applicants to be certified or qualified for certification testing at the time of hiring or within a specified time thereafter.

In 2009, the National Academies of Science (NAS) issued their report on the state of forensic science in the United States. The report was critical of the way a number of forensic disciplines are practiced. A chief criticism was that practitioners were trained but not tested (certified). Included in the first recommendation was a call to establish standards by which all forensic practitioners would be certified. In addition, the need to develop enforcement mechanisms was also identified. The report saw accreditation of forensic service providers and certification of practitioners as a mandatory requirement. However, as noted in the report, only three states, New York, Oklahoma, and Texas, have statutory requirements for accreditation of crime laboratories. Oklahoma, for example, requires all crime laboratories to be accredited but exempts latent print units provided that the work is done and testimony provided by an IAI-certified examiner.

Certifying Bodies

Although certifying bodies aim to ensure the abilities of program participants, they themselves have to be reviewed to inspire confidence that the program accomplishes its goal and provides meaningful results. To that end, the American Academy of Forensic Scientists created an autonomous body, the Forensic Specialties Accreditation Board (FSAB), whose purpose is to review certification programs and to award accreditation if the program measures up to predefined standards such as prerequisite education and training, skill testing,

periodic recertification, and adherence to the professional code of ethics.

The following professional organizations offer certification programs that have been accredited by the FSAB: The International Association for Identification (IAI), the oldest and largest association of forensic practitioners, offers a number of certification programs. The association maintains a Professional Programs Quality Assurance Governing Board that oversee the various certification boards. The program board ensures that each individual certifying board operates in accordance with their FSAB accreditation and maintains standards across the entire certification program. All IAI certifications are for a period of 5 years. Recertification requires continuing education and work experience and may require passing a recertification test. Certification is offered in the following disciplines:

Latent Print

The Latent Print certification program is the oldest of the IAI's certification programs. It is geared toward examiners who process evidence and crime scenes for friction ridge impressions and compare those impressions to known exemplars or other recovered impressions. The pretesting qualifications include academic achievement (or comparable work experience), discipline-specific training, and a minimum of 2 years work experience as a latent print examiner. Applicants must also provide character and employment references.

The test for certification involves a three-part written examination, a skill portion where the applicant must successfully compare unknown impressions to known exemplars and oral board testing relating to the ability of the examiner to properly convey their results and the underlying scientific principles of their discipline in court.

Crime Scene

The Crime Scene Certification program has the largest participation of all the IAI's certification programs. It is the only one of the programs that has multiple levels of certification:

- Crime Scene Investigator
- Crime Scene Analyst
- Senior Crime Scene Analyst
- Crime Scene Reconstructionist

The Investigator, Analyst, and Senior Analyst programs are designed for those who investigate crime scenes, collect evidence, and use their training, experience, and skills to bring coherence to the situation under investigation. Prequalification for testing involves education, experience, discipline-specific training, and character and professional references. Testing involves a written examination, the length and complexity of which is determined by the level of certification sought. Senior Analyst applicants also have a teaching/testimony/publication requirement.

The Crime Scene Reconstructionist program focuses more on the interpretation of the collective evidence found at a crime scene as opposed to crime scene processing. It also has pretesting requirements involving education, training, and experience. There is also a teaching/testimony/publication

requirement. Testing involves a comprehensive written examination and a practical exercise.

Footwear

Certification as a Footwear Examiner is for those who specialize in the collection of footwear specimens from crime scenes or evidence and compare it to known exemplars. Prequalification for testing involves education, experience, discipline-specific training, and character and professional references. Testing is by written and practical examination.

Forensic Photography

Applicants for the Forensic Photography certification must prequalify by experience, discipline-specific training, and endorsement by their employer and an associate. Testing is by written and practical examination.

Tenprint Identification

Tenprint certification is for individuals who deal with the creation, management, and comparison of fingerprint records used to maintain criminal history records and populate databases used by automated fingerprint identification systems and other biometric identification systems. Applicants for certification prequalify by education, discipline-specific training, and experience. Professional endorsements are required. Testing is by written and practical examination.

Forensic Art

The Forensic Art Certification program offers multiple certifications that are not levels as with the crime scene certification program. These are endorsements that deal with the specific aspect of forensic art in which the applicant wishes to certify. These endorsements are Composite Imaging, Facial Reconstruction, and Age Enhancement. Applicants must prequalify for testing based on experience, discipline-specific training, and professional references. Testing is by written and practical examination in the form of a portfolio review of the applicant's work.

Bloodstain Pattern

Bloodstain pattern examiners deal with the analysis and interpretation of bloodstain evidence found at crime scenes and on the evidence. Some of the analysis is based on visual pattern recognition and some involves mathematical calculations based on measurements taken from individual bloodstains. Applicants must prequalify for testing based on experience and discipline-specific training. Testing is by written examination, which includes the application of theory and mathematical calculations.

Forensic Video

The Forensic Video Certification is the IAI's newest program. It has not yet been accredited by the FSAB. It is designed for those

who are proficient at using the various tools and technologies associated with the examination of video captures. Applicants prequalify for testing based on education, discipline-specific training, experience, and professional endorsement. Testing is by written and practical examination.

All persons certified by the IAI are subject to the association's Code of Ethics and Standards for Professional Conduct. Violations are handled by a Professional Review Board (PRB). PRBs also investigate allegations of technical error or incompetence.

The American Board of Criminalistics (ABC) is made up of organizations that represent forensic scientists. Member organizations include the following:

- The American Academy of Forensic Sciences (AAFS)
- The American Society of Crime Laboratory Directors (ASCLD)
- The ASTM (originally American Society for Testing and Materials) Committee E30
- The California Association of Criminalists
- The Mid-Atlantic Association of Forensic Scientists (MAAFS)
- The Northeastern Association of Forensic Scientists
- The Midwestern Association of Forensic Scientists (MAFS)
- The Southern Association of Forensic Scientists (SAFS).

The ABC's certification program is geared toward those who work in forensic laboratories. Certification is achieved through testing in a specific discipline. Tests are offered in the following areas:

- Comprehensive Criminalistics Examination
- Drug analysis
- Molecular biology
- Fire debris analysis
- Trace evidence – Hairs and Fibers
- Trace evidence – Paints and Polymers

Tests are also offered in subjects relating to the underlying basis of criminalistics and general practices such as safety, ethics, and areas of civil and criminal law that apply to the work of a forensic scientist.

The ABC has a two-tiered structure of certification. The Fellow level is achieved on passing any of the ABC examinations and a proficiency test. The applicants must also have a minimum of 2 years experience in the specialty area for which they are being tested. The Diplomate level is designed for laboratory directors, supervisors, and educators and for those where specialty tests are unavailable. Applicants for the Diplomate certification must prequalify with 2 years of forensic laboratory or teaching experience. Diplomate candidates must pass one of the ABC tests. Both Fellows and Diplomates must have a BS/BA degree in a natural science.

Violations of the Rules of Professional Conduct are investigated by the ABC, which may enforce disciplinary action if warranted.

The American Board of Medicolegal Death Investigators (ABMDI) 'certifies individuals who have the proven knowledge and skills necessary to perform medicolegal death investigations as set forth in the National Institutes of Justice 1999 publication 'Death Investigation: A Guide for the Scene Investigator'. The certification program involves two levels:

Registry Certification (Diplomate) and Board Certification (Fellow). Applicants for certification must be currently employed, either full or part time, by a medical examiner or the coroner's office. In the case of military personnel, the applicant must be currently assigned to conduct death scene investigations. Diplomate candidates must have acquired 640 h of death investigation experience. Fellows must have been awarded Diplomate status first and have accumulated 4000 h of experience. Successfully passing a written examination is required of Diplomate applicants. Fellow applicants must pass a written examination and a practical examination consisting of an analysis of death scene scenarios. Certification is for a period of 5 years. Recertification requires continuing education and continued work experience.

Violations of the Code of Ethics and Conduct are investigated by the Board of Directors, which may also enforce disciplinary action if warranted.

The American Board of Forensic Toxicology (ABFT) certifies individuals who practice forensic toxicology. Forensic Toxicology is the application of the study of the effect of drugs and chemicals on biological systems to cases where the results may be used in court. The ABFT also has a laboratory accreditation program for laboratories that practice postmortem forensic toxicology or human performance toxicology.

Certification is on two levels: Forensic Toxicology Specialist and Diplomate of the Board. Applicants for certification as a Diplomate must have earned a degree of Doctor of Philosophy or Doctor of Science and must have taken course work in pharmacology or toxicology. They must have at least 3 years of professional experience prior to testing. Testing is by written examination. Certification is for 5 years. Recertification is based on continuing education and professional practice.

Applicants for certification as a Forensic Toxicology Specialist must have earned a degree in one of the natural sciences and have adequate course work in biology and chemistry. Three years of professional experience is needed prior to testing. Testing is by written examination. Certification is for 5 years. Recertification is based on continuing education and professional practice.

Diplomates and Specialists must adhere to the Code of Ethics. Certifications may be suspended or revoked by the Board for cause, subsequent to an investigation.

The Board of Forensic Document Examiners (BFDE) offers certification as a Diplomate of the BFDE. Applicants for certification must have a baccalaureate degree, discipline-specific training, current professional employment as a document examiner, and character and professional endorsements. The applicant must also have access to laboratory equipment used in the profession. Testing involves a written examination and a performance test that can cover handwriting, hand printing, altered documents, and paper and printing devices. Tests are administered, proctored, and graded by the Occupational Research and Assessment, Inc. Certification is for a period of 5 years.

Certificate holders must adhere to the Code of Ethics and Code of Professional Conduct. Violations are investigated by the Ethics and Grievance Council. Sanctions are enforced by the Board.

The objectives of the American Board of Forensic Document Examiners, which was established in 1977 with a grant

from the US Department of Justice, 'are to establish, enhance, and maintain standards of qualification for those who practice forensic document examination and to certify, as qualified specialists, those voluntary applicants who comply with the requirements of the Board.' Applicants must have earned a baccalaureate degree and have completed a 2-year training period in forensic document examination. They must be actively employed as a forensic document examiner. An endorsement from three document examiners certified by the board is required.

Testing for certification involves a written examination, practical problems, and an oral examination. Successful completion of the certification process entitles one to the title of Diplomate of the ABFDE. Certification is for a period of 5 years. Recertification is attained by earning continuing education credits during the certification period.

Violations of the Board's ethical or professional conduct rules or questions of competency are handled by a Professional Review Committee.

The International Board of Forensic Engineering Sciences 'certifies professionals with degrees in the many traditional engineering disciplines such as mechanical, electrical, civil, industrial, and chemical engineering, etc., along with those in the engineering-related physical sciences including physics, chemistry, metallurgy, geology, meteorology, biomechanics, optics, and computer science, etc.' Applicants must have a minimum of a baccalaureate degree in one of the engineering sciences, 3 years experience giving testimony at trials or depositions as a forensic engineer, and a period of full-time employment in an engineering science or physical science.

Testing involves a written examination dealing with hypothetical situations and an oral examination involving a review of past work. Successful completion of the testing process entitles one to the designation of Diplomate of the IBFES. Certification is for a period of 5 years. Recertification is based on continuing education and professional development and practice.

Complaints against a Diplomate for ethical or professional shortcomings are handled by the Board's Ethics Committee.

The American Board of Forensic Odontology (ABFO) manages a certification program for Doctors of Dental Surgery (DDS) and Doctors of Dental Medicine (DMD) who specialize in the identification of bite mark evidence and identify individuals based on their teeth. Applicants for certification must be a DDS or DMD and must have professional experience that includes attending a set amount of forensic organization meetings; participating in forensic meetings by presenting papers, lectures, or panel discussions; active association with a medical examiner/coroner's office or law enforcement agency for at least 2 years; observing autopsies; performing forensic dental cases that include identifications, jaw resections, and radiographs; and offering testimony in court or by deposition. Three letters of recommendation from peers are also required.

Testing is by written and oral examination. On successful completion of the test, the applicant achieves Diplomate status. Certification is for a period of 5 years. Recertification is through continuing education.

Complaints are investigated by the Ethics Committee. The ultimate disposition is left to the organization's Board of Directors.

The American Board of Forensic Anthropology (ABFA) certifies practitioners who, through study and analysis, assist in the identification of human remains. Those certified as Diplomates are considered to have attained the highest level of achievement in Forensic Anthropology. Applicants must have earned a doctoral degree in anthropology and have 3 years experience in forensic anthropology. They must submit cases that were reported to a medical examiner, coroner, or law enforcement agency for review by the Board. Three letters of recommendation are required.

Testing is by written and practical examination. Certification is for a period of 3 years. Recertification requires continued education and professional experience.

Violations of the Rules of Ethics and Conduct are investigated by the Ethics Committee, which can recommend actions to the Board.

The National Association of Forensic Counselors (NAFC) offers certification for counselors working with criminal offenders in the criminal justice system, corrections including probation and parole, addictions, and mental health programs. Applicants for clinical certification must have a master's degree in their field and be licensed where required. They must have 2 years full-time experience in their specialty. Three letters of recommendation from peers are required. Clinical certifications are offered in the fields of forensic counselor, criminal justice specialist, domestic violence counselor, sex offender treatment specialist, juvenile treatment specialist, and sentence mitigation specialist. Certifications are renewed annually. Renewal is based on continuing education.

Nonclinical certifications are for applicants who do not have a master's degree or otherwise do not meet the requirements for clinical certification. Applicants must have a minimum of a baccalaureate degree. They must be employed at a facility that deals with criminal justice clients and must have worked under the supervision of a clinically certified counselor or other licensed practitioner. Nonclinical certification is available for the same fields as clinical certification. Certifications are renewed annually and renewal is based on continuing education.

Certifications are available for those practicing addiction specialties in the following areas: chemical dependency counselor, master addictions counselor, master social work addictions counselor, forensic substance abuse specialist, and forensic addictions specialist.

Testing is by written examination covering five domains: Clinical Assessment and Treatment Planning, Counseling and Case Management, Psychological Dynamics of Criminal Behavior and Substance Abuse, Criminal Justice Processes, and Legal, Ethical and Professional Responsibilities. Violations of standards are investigated and handled by the governing board.

The International Association of Computer Investigative Specialists (IACIS) offers a certification program for examiners of computer related media who analyze the recorded data. Computer Forensics, as defined by the IACIS, is "the acquisition, authentication, reconstruction, examination and analysis of data stored on electronic media." A Certified Forensic Computer Examiner is expected to be able to recover data from electronic media as well as have a thorough understanding of computer operating systems, filing systems and applications, and how these factors affect data.

Applicants for certification are required to have 72 h of training in computer or digital forensics that cover the core competencies identified by the program. This may be obtained independently or by enrolling in a training program sponsored by the IACIS. Applicants must first successfully complete a series of mentored practical examinations before becoming eligible to take the written certification exam. Certification is for a period of 3 years. Recertification requires 60 h of continuing education in the core competencies and successful completion of a proficiency test.

Certificants must agree to abide by the code of ethics. Alleged violations of the code are investigated by the Ethics Subcommittee, operating under the direction of the Director of Ethics. The subcommittee reports its findings to the Board of Directors, which may decide that the charge is unfounded or revoke a certification, if appropriate.

Other Certification Programs

Lacking accreditation can cast doubt on the value of a particular program. However, not being accredited does not mean that the program is not well designed. There are many other organizations that offer certification programs. Of note are three programs involving disciplines not covered by programs mentioned thus far.

The Association of Firearm and Tool Mark Examiners (AFTE) offers certification in three areas:

- Firearm Evidence Examination and Identification
- Toolmark Evidence Examination and Identification
- Gunshot Residue Evidence Examination and Identification

Applicants for certification must be members of the AFTE. They must possess training and experience as outlined in the training manual, 3 years paid experience as a court-qualified Firearms/Toolmark examiner, and a baccalaureate degree. Testing is by written and practical examination. Certification is for 5 years. Recertification is through continuing education and proficiency testing.

Violations of the Code of Ethics are investigated by the Certification Committee, which may also enforce sanctions if warranted.

The American Board of Pathology (ABP) offers certification in anatomic pathology, clinical pathology, or combined anatomic and clinical pathology. They also offer certification in a variety of subspecialties including forensic pathology. Applicants must have graduated from medical school and completed a graduate medical education program in pathology, must be licensed to practice in their state, must be endorsed by the pathology training program director and faculty, and must successfully complete a voluntary evaluation process through the ABP. There are also requirements for participation in an accredited training program, and applicants for anatomic pathology certification must have completed 50 autopsies. Certification in a subspecialty requires additional training and examinations.

Testing is by written and practical examination. Certification is for a period of 10 years. Recertification is by

participation in a maintenance of certification program that examines professional standing, commitment to learning and involvement in periodic self-assessment, cognitive expertise, and performance in practice.

The Forensic Nursing Certification Board offers certification for Sexual Assault Nurse Examiners (SANE). Certification is available for those dealing with adults and adolescents (SANE-A) and those who deal with pediatrics (SANE-P). The Board operates through the International Association of Forensic Nurses.

Applicants for certification in the United States must hold an active license as a registered nurse (RN). Additional requirements may be necessary for those practicing outside the United States. Applicants must also have completed specialized training in an adult/adolescent or pediatric sexual assault nursing education program. Two years experience as a practicing RN or first-level general nurse in the country in which they are licensed is required for SANE-A applicants. Three years experience as a practicing RN or first-level general nurse in the country in which they are licensed is required for SANE-P applicants. Other training and experience requirement formulae are available. Certification is for a period of 3 years. Recertification is based on continuing education. Testing is by written examination.

The Board may revoke certification if it is found that the applicant provided false information concerning their qualifications or that the applicant's licensure status has changed. Revocation is also warranted if their SANE status is misrepresented.

Licensing and certification programs can neither guarantee that licensed and certified practitioners will perform flawlessly nor assure ethical behavior. Some certification programs claim to test for basic competency. Others believe that they are testing for excellence. But, practitioners who have opted to participate in a certification program have demonstrated their knowledge of and skill at their discipline. One should be able to reasonably rely on the work of certified forensic practitioners.

Continuing Professional Development

SH Neal, Morgantown, WV, USA

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Class A group of individuals or students who meet regularly to study a particular subject under the guidance of an instructor or teacher.

Continuing education The structured educational activities designed or intended to support the continuing development and to maintain and enhance the forensic scientists' competence.

Continuing professional development The mechanism through which an individual remains up to date or advances to a higher level of expertise, specialization, or responsibility.

Course A program of instruction in a particular field of instruction.

Distributed learning Educational methods that use distant or distributed education such as video, the Internet, and electronic multimedia.

Laboratory practicals An educational testing situation that emphasizes hands-on methods and procedures.

Training The formal, organized process through which a forensic scientist reaches a level of scientific knowledge and expertise required to perform specific forensic analyses.

Forensic scientists in a variety of disciplines require a complex combination of skills, knowledge, and experience in order to carry out their role effectively. It is widely recognized that maintenance of skills and knowledge over time plays an important part in ensuring that standards of practice are current and that competence in the position is promoted. Continuing professional development is a framework that allows people to maintain knowledge, skills, and education in their careers beyond the basic requirements of their profession. Continuing professional development is beyond meeting basic requirements to facilitate professional development and competency as a forensic scientist. It is the method through which a forensic science practitioner remains up to date or progresses to a higher level of expertise, specialization, or responsibility in the field.

Continuing professional development is the regular maintenance, improvement, and broadening of knowledge and skill, and the development of qualities necessary for the performance of professional and technical duties throughout the forensic practitioner's career. Continuing professional development includes maintaining competence, skill enhancement, and other professional activities, such as keeping up to date with new techniques, which will better the practitioner in their position. It is a lifelong process of active participation in learning activities that assist in developing and enhancing professional practices and techniques.

It is important that continuing professional development is measured, structured, and documented. To measure continuing professional development, assessment mechanisms need to be in place. These measurements can be oral or written exams or reports, peer-reviewed publications, evaluations by instructor, relevant laboratory exercises and practical, and observation of technical performance. Continuing professional development classes or courses should follow a predetermined guideline that includes learning objectives, instructor qualifications, detailed syllabus, detailed course description, assessment to show outcomes, and documentation, such as a certificate of completion or continuing education (CE) credits. Following these guidelines allows for standardized training and lets the professional know the quality of the training.

Forensic science practitioners require continuing professional development and training. The forensic scientist has an obligation to remain current in their field with CE. The laboratory management also has a responsibility to provide support and opportunities for scientists to participate in continuing professional development. The practitioner must be aware of new developments or scientific advances in forensic science techniques and research in the forensic science disciplines to maintain his or her skill level and knowledge of the most current techniques and methods. If the practitioner is not aware of the new techniques that may produce better results, he or she may be questioned in a court of law as to why this technique was not being used.

When a forensic science practitioner is newly hired, that individual requires training to build knowledge and competency. The discipline or specialty area of the practitioner normally determines the amount of time and the type of training that is needed. For example, a firearms and tool mark examiner may take up to 3 years of training before they are permitted to do case work independently, whereas a forensic drug chemist may require only 6–12 months of training. This type of training may be part of the new hires position and may be separate from CE. These individuals may want to seek additional training or CE that will enhance their required training. Requirements for continuing professional development training may vary by forensic discipline and agency.

Types of Continuing Professional Development

Continuing professional development for forensic science practitioners requires education and training. Education and training are required on a continuous basis to maintain expertise, update knowledge and skills, and keep up with advances in equipment and changes in technology. Practitioners must be aware of new developments and scientific advances in forensic science techniques and research to remain competent to analyze evidence. The practitioners need to complete discipline-specific CE or training to stay abreast of these advances. They

also need the CE and training for certification or laboratory accreditation purposes, for scientific and technical working groups' requirements, to be in compliance with accepted accreditation standards, or to learn new skills as part of their career development.

Continuing Education

CE is critical for all forensic science practitioners. CE for the forensic scientist is structured educational activities designed or intended to support their continuing development and to maintain and enhance their competence. CE should promote problem solving and critical thinking and be applicable to the practice of forensic science. Some commonly used approaches to CE are instructor led, professional conferences/seminars, distributed learning, apprenticeship, residency, internship, teaching and presentations by trainee/employee, and independent learning classes or courses.

The quality of CE for the forensic scientist should follow specified minimum requirements and be consistent with recognized, peer-defined standards that are set by specific accrediting bodies or forensic disciplines (e.g., ASCLD/Laboratory Accreditation Board, Scientific Working Groups). CE training programs normally follow a set structure that includes learning objectives, instructor qualifications, a detailed syllabus, performance goals, assessments, pertinent activities or practical exercises, and competency testing. These programs follow the standards that are established by the crediting body (i.e., organizations that issue credits or continuing education units (CEUs)). On completion of CE courses or training, the forensic scientist should be assessed through written or oral examinations, laboratory practical exercises, and/or mock trials.

Most CE content focuses on a specific topic or discipline, with some content focusing on foundational topics such as ethics, laboratory safety, policies and standard operating procedures, expert testimony, evidence handling and collection, and communication and report writing. These courses are usually geared toward practitioners who are new to the field, however, may serve as a refresher course for seasoned professionals. The discipline-specific courses normally include history, methodologies, validation studies, instrumentation, testimony related to the discipline, statistics, practical exams, and relevant literature.

Training

Training refers to the formal, organized process through which a forensic scientist reaches a level of scientific knowledge and expertise required to perform specific forensic analyses. There are different training needs for forensic science practitioners depending on their discipline, years of experience, and level of position or rank. All members of the crime laboratory and forensic science practitioners need an overview and sometimes training in subjects or topics such as the legal system, ethics, criminal justice system, basics of forensic science, quality control, effective expert testimony, and safety procedures. The bench or operational scientist needs specific training to stay current in practical and theoretical issues such as performing analyses and applying new or updated methods. Supervisors may need training in topics such as quality assurance, case file

review, and basic management skills. Crime laboratory managers, who were most likely bench scientists, may need training in leadership, customer service, fiscal management, project management, and human resource management. Training can be completed through short courses in different formats like in-service, web-based, or on-the-job training.

As with CE, training content focuses on peer-defined standards on a specific topic or discipline, with some content focusing on foundational topics such as ethics, laboratory safety, policies and standard operating procedures, expert testimony, evidence handling and collection, and communication and report writing. Training can be geared toward practitioners who are new to the field or as a refresher course for seasoned professionals. The discipline-specific courses may include history, methodologies, validation studies, instrumentation, testimony related to the discipline, statistics, and relevant literature.

Training programs should follow a structure, which includes learning objectives, instructor qualifications, a detailed syllabus, performance goals, assessments, pertinent activities or practical exercises, and competency testing. On completion of the training, the forensic scientist should be assessed through written or oral examinations, laboratory practical exercises, mock trials, and/or assessment of technical performance by appropriate senior staff.

Sources of Continuing Professional Development

Continuing professional development sources may be internal and/or external to a forensic science laboratory or agency. Internal sources can range from the technical leader of a discipline to the crime laboratory manager to hiring an expert to teach a course at the laboratory and in-service training sessions. External sources of continuing professional development can include, but are not limited to, government agencies, academic or training institutions, private industries, professional societies, or experts of the discipline.

Administration of Continuing Professional Development

The delivery of continuing professional development can be administered in several different forms. In the forensic science community, the most popular forms of delivery are symposia, workshops, seminars, lectures, professional meetings, and in-service or short courses. These delivery methods usually offer a number of topics by a range of service providers to include professional societies and associations, academic institutions, forensic experts, private forensic institutions, and Federal and State laboratories.

Alternate delivery systems for forensic science continuing professional development are also available. This includes electronic media (i.e., CDs and DVDs), web-based instruction or distance learning (i.e., online courses, videos, and audio recordings), distributed learning, and video conferencing (i.e., can be live or previous recorded instruction). With these types of delivery systems, many more practitioners can participate in the training or CE without leaving their agency. This type of training can benefit the agency because of minimal cost and time effectiveness.

However, certain types of training or CE require face-to-face or hands-on participation and evaluation. This type of training is conducted in the aforementioned delivery forms such as workshops and short courses.

Education and Accreditation in Forensic Science

TM Palmbach, University of New Haven, West Haven, CT, USA

© 2013 Elsevier Ltd. All rights reserved.

As a scientific discipline, forensic science has its roots within the natural sciences, and as such practitioners and researchers must be exposed to a quality education, heavily structured in math and sciences. As the field has developed and expanded, so has the need for enhancement and expansion of relevant educational programs. There now is so much diversity within the large paradigm of 'forensic science' that it requires a complex highly diverse educational system to meet the needs of today's and tomorrow's forensic scientists. It is no longer uncommon to see a bench level forensic science entering the work force with an earned doctorate; yet, there is room for successful career tracks with individuals possessing Master of Science or Bachelor of Science degrees.

Historical Perspectives

Elements of forensic science have been around for well over a century. Disciplines such as anthropology, fingerprint identification, firearms analysis, basic serology, and blood stain pattern analysis can be traced back to the late 1800s. Early pioneers in the field were generally scientifically trained researchers who sought to solve a problem faced by the police or criminal justice system. Once introduced, law enforcement embraced the utility of these methods and began to implement them in crime-solving strategies. As these early developments were used with success, they were often incorporated into police agencies, and practitioners learned the skills on the job or with minimal training. The concept of forensic science as an academic program worthy of an academic credential or degree took much longer to develop.

In 1946, Michigan State University took claim to be the first US University to offer a degree program in forensic science. University of Lausanne in Switzerland offered a course in legal photography at the beginning of the twentieth century and as such proclaimed to be the oldest academic institution to offer coursework in forensic science. The growth and development of forensic science programs was relatively slow. Even as recent as the late 1980s, the option of forensic science as a collegiate major was relative unknown. There were approximately one dozen American Universities that were offering forensic science as a major. Further, most of these programs graduated a hand full of students each year from this obscure major.

During these early years of forensic science, the expectations of the criminal justice community and scientific limitations of the field created an environment where a major emphasis on formal education was not necessary. For starters, society simply did not have expectations or demand the interjection of science into crime solving that it has obtained in this current CSI crazed world. A majority of criminal matters were resolved with good old-fashioned police work. Key elements of those investigations included confessions, eye witness testimony, and a solid circumstantial case constructed through

investigative efforts. Over the years, it has become apparent that these investigative methods while often successful could also yield false or misleading investigative information. As forensic science began to expand and become available to everyday police work, the focus began to shift toward the scientific answers.

For most of the twentieth century, the availability of forensic science to assist in solving crimes was focused primarily on disciplines outside the direct realm of natural sciences, biology, chemistry, and physics. Available disciplines included fingerprints, firearms evidence, crime scene photography and evidence collection, and handwriting analysis. These pattern-based, identification disciplines were not the subject of formal education courses, not to mention entire degree programs. Potential apprentices learned these skills under the tutelage of a skilled practitioner, who most often learned in the same manner. Under this model, it was possible for these fields to further develop and refine their methodologies by simply assessing what works and what does not. For the most part, what was lacking was an understanding of the fundamental principles upon which these disciplines were based. Certainly, more complex mechanisms such as the statistical analysis of the data and proper expression of that data were not addressed. Further, a majority of this work was conducted by police agencies, and outside the purview of scientists and researchers.

As disciplines more closely associated with biology or chemistry emerged, the need for academically trained practitioners was evident. Disciplines such as Toxicology and Serology began to expand in both practical application and research. Laboratories at the city, state, and federal levels were created to house these more traditional science specialties. In some jurisdictions, there was a move to merge the traditional services, such as photography and fingerprint analysis, into the emerging laboratories dedicated to chemical and biological-based analysis of physical evidence. Other jurisdictions, some of which still exist, elected to keep the traditional police-based identification disciplines separate from the natural science-based methodologies. During these early and transitional years, the educational requirements for these different positions began to diverge. Many of the practitioners in the police-based disciplines had no more than a high school education, but did possess some professional training and often had very extensive experience within their specialty.

Forensic Science as a Recognized Discipline

Somewhere around the late 1980s, forensic science underwent a major transformation. Remarkable advances based on high-quality research were emerging. In England, Dr. Alec Jeffreys was informing the world of his DNA fingerprinting techniques and opening the doors to one of the most powerful and robust scientific tools ever employed in human efforts to solve crimes

and obtain justice. Prime time television introduced the public to the abilities to use complex scientific methodologies to solve crime. The OJ Simpson trial was the first of many trials which would take a forefront in modern media and interest. These early cravings were further fueled by the introduction of countless TV programs, movies, and novels dedicated to crime scene investigation – CSI and forensic science. The criminal justice system responded with a huge new focus on the analysis of physical evidence. And with that new focus arrived an opportunity for a career path within the many disciplines of forensic science, most of which would require an educational degree. The rapid growth of the forensic science educational community was sparked.

1999 NIJ Review of Forensic Science

In March 1997, the National Institute of Justice (NIJ), the National Institute of Standards and Technology (NIST), and the American Society of Crime Laboratory Directors (ASCLD) held a conference to assess the current state of forensic science and forensic laboratories in the United States. One of the focus points of this study was to enhance the development of new technologies and create methods to more quickly integrate these new technologies in functional forensic science labs. Very closely associated with this highlighted need was a finding which declared that the training needs of the forensic community were immense. An initial focus was to develop and integrate training programs to assist current bench level scientists in acquiring skills and knowledge associated with these new technologies. However, it was also apparent that future employees would need to be properly educated and trained as they began their careers in forensic science. There was a focus on the need to structure this training to address both theoretical as well as practical issues associated with the new and developing technologies.

One of the proposals that emerged from this study was to create opportunities for universities to offer academic credits for relevant short courses offered at other institutions. It was believed that the ability to obtain academic credits may encourage greater participation in these training programs, as well as provide credibility for a quality professional training module. Of course, there would be a need for funding to implement and provide this level of training. An early target was to provide funding for accredited academic institutions that could provide graduate level forensic science research so that appropriate new technologies can be developed. Also highlighted in this study was a need for training key areas such as quality assurance and expert witness testimony. Finally, as a result of this inquiry, it was determined that there were nine common disciplines provided by the forensic laboratories of that day. Those disciplines were:

- Latent Print Examinations
- Questioned Document Examinations
- Firearms/Toolmarks and Other Impression Evidence Examinations
- Crime Scene Response and Related Examinations
- Energetic Materials (Explosives and Fire Debris Examinations)
- Postmortem Toxicology and Human Performance Testing

- Forensic Biology and Molecular Biochemistry
- Transfer (Trace) Evidence Evaluation
- Controlled Substance Examinations

The work of this committee was completed and published in February 1999 by the US Department of Justice, NIJ, *Forensic Sciences: Review of Status and Needs*.

TWGED

As a result of a study which commenced in 2001, a team under US Department of Justice, NIJ issued a second major report on the status of forensic science, and focused on educational aspects. This report was published in 2004. *Education and Training in Forensic Science: A Guide for Forensic Science Laboratories, Educational Institutions, and Students*. This report was the work product of the Technical Working Group on Education and Training in Forensic Science (TWGED).

The primary finding was that educational programs in forensic science must have a strong background in natural sciences and include extensive laboratory coursework. Students in graduate programs can transit from theoretical concepts to discipline-specific knowledge, and should contain a substantial research component. In addition to articulating curriculum requirements, this report addressed other qualifications necessary for a career in forensic science. Future candidates were informed of the need for personal integrity and honesty, and that they would likely be required to submit to extensive background tests and perhaps drug testing. In addition, credit history, driving record, past work performance, medical exams, and polygraph examination may all play a factor in their hiring process. Finally, these recommendations articulated what a model forensic science program would look like and what were the necessary resources, for example, faculty and facilities required to accomplish this mission.

Undergraduate Curriculum

A detailed sample curriculum was suggested for all forensic science undergraduate programs. This curriculum contained a natural science core, specialized science core courses, forensic science course work, forensic science laboratory courses, and additional upper level course work. There was an understanding that different academic programs may have tracks or overall specializations such as biology, chemistry, toxicology, or one of the identification disciplines.

A recommended natural science core consisted of 34–38 credit hours including:

- General Biology
- General Chemistry
- Organic Chemistry
- Physics
- Calculus
- Statistics

A specialized core was 12 credit hours and would vary among the different program tracks or focus. For example, a biology track program would offer Biochemistry, Genetics,

Instrumental Analysis, and Molecular Biology. A chemistry track would require Quantitative Chemistry, Inorganic Chemistry, Instrumental Analysis, and Physical Chemistry.

The core forensic science elements may be covered in specific course or as portions of required courses. These mandated six credit hours must cover the following topics:

- Introduction to law and justice system
- Ethics
- Professional practice
- Overview or forensic science survey course
- Evidence identification, collection, and processing
- Quality assurance
- Courtroom testimony
- Technical and scientific writing

In addition, there must be an additional nine credit hours of forensic course work, which contained a laboratory component. Again, there could be minor variations to accommodate different tracks. Required courses consisted of Forensic Biology or Chemistry, Microscopy, Physical Methods, and a relevant internship experience.

Finally, students were required to take an additional 19 credit hours that would give them greater depth in their specific concentration. Common course topics include Introduction to Criminal Justice, Legal Evidence, and Public Speaking. Biology tracks students would take Cell Biology, Microbiology, Population Genetics, and Immunology. Chemistry-based students would take Advanced Instrumental Analysis, Drugs, Analytical Toxicology, Materials Science, and Pharmacology. Students in other tracks may take courses such as Image Analysis.

Graduate Curriculum

Graduate programs in forensic science must require a baccalaureate degree in forensic science or a natural science. Education at this level should move beyond theoretical concepts and provide students with critical thinking ability, problem-solving skills, and advanced discipline-specific knowledge. Consistent with other science-based graduate programs, these forensic science programs need to incorporate a research component.

Regardless of their specific focus, a forensic science graduate program should contain curriculum that address the following topics:

- Crime scenes
- Physical evidence concepts
- Law/science interface
- Ethics and professional responsibility
- Quality assurance

Additional specific courses would address analytical chemistry and instrumental analysis, drug chemistry, microscopy, forensic biology, and pattern evidence.

Forensic Science Education Programs Accreditation Commission

Creation of the Forensic Science Education Program Accreditation Commission (FEPAC) has undoubtedly improved the

landscape of forensic science educational programs. With these standards as minimum requirements, consumers of forensic science, from prospective students to laboratory directors, now have assurance of the quality of accredited programs. As FEPAC expands into other areas of the discipline (such as with digital evidence in 2010) and into a wider array of degree programs, the level of educational rigor and scientific validity is expected to increase as well.

NAS Report – Strengthening Forensic Science in the United States

In 2009, the National Academy of Sciences (NAS) issued a comprehensive report on the current status of forensic science in the United States, including recommendations for research, technology assessment, and increased education. In *Strengthening Forensic Science in the United States: A Path Forward*, the call for research was directed at all disciplines in forensic science and was seeking methods for determining the limitations of forensic science, integration of statistical analysis into many areas, and to address the impact of sources of variability and potential bias. Several of the recommendations will require interaction of universities and academic based research models.

Recommendation 3 stated that research is needed to address issues of accuracy, reliability, and validity in the forensic science disciplines. A logical and effective way to address this recommendation is for collaborative efforts between practitioners and functioning crime labs and academic institutions that have the time and expertise to design and conduct relevant scientific testing. Ideally, academic programs involved in this process would have faculty with practical forensic science experience or maintain a very close connection with practitioners so that the issues studied are germane to the daily operations of the modern forensic science laboratory. Another advantage in the partnership with academic programs is the interaction of students, future laboratory workers, with the issues and the scientific research and responses to resolve those issues.

Clearly, there are funding needs associated with this type of research, but the NAS report addressed those needs and made recommendations for future funding and grant opportunities.

Recommendation 7 called for accreditation and individual certification of forensic science professionals. This problem can be addressed by approaches that deal with future employees as well as in-service training and certification for current employees. Accredited academic institutions are already available to ensure that future practitioners in forensic science possess the necessary skills and obtain required certifications. These same academic institutions can also provide professional training courses and certification programs. Several universities in the United States house both academic forensic science programs as well as forensic science institutes that service professionals.

Recommendation 10 directly addressed educational issues. The focus of this recommendation was to attract students in physical and life sciences to pursue graduate studies in fields aligned with forensic science disciplines. There is a need for funding to assist in attracting top students. Further, educational initiatives are needed for the legal community related to forensic issues.

Future Educational Needs

Given the recommendations of the NAS report, and need for the forensic science community to further study existing methodologies as well as properly validate emerging technologies, the need for quality education will only increase. In the early years of forensic science, up until around 1980s, many practitioners had only a high school education and some on-the-job training. As forensic laboratories grew in scope and function, bench scientists commonly entered the field with a natural science or forensic science baccalaureate degrees and more commonly Master of Science degrees. As research increases to address these key issues, more PhDs will be necessary to conduct and mentor the appropriate level of research and scholarly inquiry.

Currently, the United States educational system is not offering a Doctor of Philosophy degree in forensic science. Those with PhDs working in forensic science laboratories and teaching in forensic science programs generally possess earned doctorates in analytical chemistry, toxicology, molecular or cell biology, or a similar scientific discipline. There are some criminal justice or criminology programs that offer earned doctorate degrees in which the focus is a forensic science discipline. It is still too early to predict how many institutions will elect to develop a pure forensic science doctorate.

However, in Europe, there are several universities offering a PhD in forensic science. University of Lausanne in

Switzerland claims to be the oldest forensic science program in the world. In addition, several countries in the Middle East and Asia are developing forensic science programs for practitioners as well as academic programs at undergraduate and graduate levels. The demand for scholarly research, need to develop and integrate new technologies, and a very competitive employment picture, all bode well for the educational community dedicated to educating current and future forensic scientists.

Introduction

Ethics in the forensic sciences is complex and challenging, as a result of functioning at the interface of science and law – two major disciplines with differing methods, values, and goals. The law needs to obtain definitive answers in order to resolve disputes promptly and render justice. In contrast, science reaches tentative conclusions, subject to change with further evidence. Forensic science applies science to legal issues, but many differences exist between legal ethics and either scientific or professional ethics. There are specific ethical requirements for each scientific discipline with additional ethical requirements whenever scientific skills are applied to legal matters. Frequently, the two ethical requirements supplement each other. Many scientific disciplines facilitate forensic ethics by addressing the ethical aspects of the application of that discipline to legal issues, but not all disciplines do so. Whenever these requirements conflict, ethical dilemmas are created. Although there are many potential ethical problems in forensic science, most problems can be resolved by following codes of ethics or standards of good forensic practice.

Forensic Science Ethics and Personal Ethics

Forensic science ethics is the ethics of applying science to law. Many ethical facets in forensic science are controversial. Some forensic scientists attempt to resolve ethical disputes by making an apparently arbitrary distinction between ‘ethics’ and ‘morals’. However, these terms have been used interchangeably in philosophy for many years. The arbitrary distinction between ‘ethics’ and ‘morals’ enables those forensic scientists to avoid many ethical dilemmas by labeling certain ethical problems as only personal moral issues. Such ethical matters and dilemmas are thereby excluded from scientific and professional ethics discourse and consideration. The more appropriate distinction would be between personal ethics or morals, current professional and scientific ethics and the practitioner’s view of what should be professional and scientific ethical behavior. Most issues can be considered from either a personal or a scientific and professional ethical perspective, even though complex ethical problems may not lead to a consensus.

In the personal sphere, ‘ethics’ or ‘morals’ refer to the concerns forensic scientists have that are based on personal ethical (moral) or religious considerations not derived from their professional and scientific roles. In the professional and scientific spheres, ‘ethics’ is the term traditionally used. ‘Ethics’ in this context refers to fundamental foundational rules or guidelines regulating conduct in scientific and professional disciplines or forensic science organizations. In contrast, rules of

conduct or matters of etiquette are less fundamental matters that should be distinguished from ethics.

Organizational Forensic Science Ethics

For various reasons, not all professional and scientific organizations have ethical requirements or methods of enforcing them. When an organization does enforce its ethics, due process or procedures are required both ethically and legally, in which accused members have an opportunity to hear the charges against them and present a defense. The advantage of ethics enforcement by a forensic science organization is that knowledgeable peers oversee one another. Otherwise such oversight may be taken over by outsiders, who may be insufficiently familiar with the discipline or profession to be able to be fair and effective.

Ethical requirements ideally should be enforceable. They should address minimally acceptable professional and scientific behavior. Behavior below these standards should result in a finding of an ethical violation with appropriate punitive sanctions. Sanctions can range from warnings and reprimands, to suspension and expulsion from an organization. A limitation on the ability of organizations to enforce ethical standards is that they cannot enforce ethical standards and requirements on nonmembers or on individuals who withdraw from membership. However, some organizations publish the fact that a member resigned from the organization while under an ethics investigation, in disciplines in which licensing boards have authority, licenses could be suspended or revoked.

Although it is essential to meet basic minimal ethical requirements, the attainment of only a minimal threshold of ethical practice does not necessarily indicate good forensic practice. Failure to find an ethical violation is far from meaning that the professional or scientist necessarily is displaying impeccable ethics. Like the ‘not guilty’ adjudication in legal proceedings, it may mean only that there is an insufficient basis to prove that a practitioner has violated forensic science ethics.

Basic Minimal Ethics and Aspirational Ethics

Some organizations distinguish between ethical requirements representing basic minimal requirements, and aspirational standards or standards of good forensic science practice. Although many organizations confuse these two types of ethical standards, a clear distinction is important so that forensic scientists can determine which provisions represent basic minimal standards that must never be violated, and which represent a higher ideal threshold of desirable and exemplary

conduct. The aspirational provisions represent desirable standards towards which forensic practitioners should strive. 'Good' forensic scientists will do so. In contrast to minimal standards, failure to achieve aspirational standards should not lead to sanctions. Sometimes, there could be an acceptable reason for not meeting the standards of good forensic practice.

An aspirational standard may sometimes be unenforceable because an assessment of the intent of the forensic scientist may be necessary in order to evaluate the behavior. Since intent is subjective, its determination may be difficult, if not impossible, to ascertain. Nonetheless, a good forensic scientist will try to meet the aspirational standard. Alternatively, a standard may be potentially enforceable, but may not be a minimal standard meriting sanction. Instead it might represent more a matter of desirable or good forensic practice.

Poor forensic practice does not necessarily mean unethical practice. Some inadequate forensic evaluations might represent lack of knowledge or failure to keep up-to-date in a forensic science discipline. The appropriate action in such instances might involve education rather than a punitive sanction. Other inadequate evaluations may result from time pressure and/or overwork that may contribute to overlooking some important aspects of a case. Although an evaluation may be inadequate, the negligence might not be of sufficient gravity to violate a basic minimal ethics requirement.

Codes of Ethics in Forensic Science Practice

Organizations like the American Academy of Forensic Sciences have developed a code of ethics and conduct that the organization enforces. The ethics code states that members 'shall refrain from providing any material misrepresentation of education, training, experience or area of expertise'. It also requires members to 'refrain from providing any misrepresentation of data upon which an expert opinion or conclusion is based'. Additional provisions are part of the code of conduct. They are designed to prevent members from falsely claiming to represent an organization and from engaging in conduct, adverse to the best interests and purposes of the organization. Such transgressions of a code of conduct may violate the rules of the organization but may not represent violations of fundamental forensic scientific ethics. The code of ethics and conduct also has provisions describing due process or procedures.

When enforcing a code of ethics, the following questions, as enumerated by Rosner, should be answered:

1. What provision is the member accused of violating?
2. What are the criteria for that provision?
3. What are the relevant data?
4. What is the reasoning by which it is determined that the member has or has not violated the specific provision?

It is important to write ethics provisions clearly in order to prevent ambiguity that could result in an ethics hearing degenerating into a popularity contest. For example, in the absence of clear guidelines, there is a danger that a verdict could primarily become dependent on whether a hearing panel likes an accused individual, whether the accused person's views on a controversial issue are popular, or whether the accused is part

of the 'in' group. As a result, the actual seriousness of the ethics offense would become much less relevant, with less effort expended towards determining exactly what happened and for what reason, thus obscuring the stated goal of the hearing.

If there are sections of the code that potentially are unclear to a reader, clarifying interpretations should be disseminated to the organization's membership. It is essential for members to have information in advance about the specific types of conduct that are prohibited (minimal standards), with a clear distinction from those that are encouraged (aspirational standards). If there is any potential ambiguity, a way must be found to provide the necessary clarification. One possible means is to print an explanation of the issue in the organization's newsletter.

Standards for Good Forensic Practice

Aspirational standards are standards of good practice or even excellence. Good forensic practitioners should strive to attain these standards despite the fact that only minimal basic ethical standards are subject to enforcement. The American Academy of Forensic Sciences' Committee on Good Forensic Practice has developed the following Standards for Good Forensic Practice.

1. Forensic scientists generally should follow the standards of their respective disciplines. They should apply with care any assessment methods, technical skills, scientific, and other areas of specialized knowledge, to legal issues and questions. They should always strive to do high quality work.
2. Forensic scientists should strive to keep current and maintain competence in their scientific disciplines. Although competence at minimum should be a goal, forensic scientists should strive for excellence.
3. Forensic scientists should demonstrate honesty and should strive for objectivity, by examining scientific questions from all reasonable perspectives and by actively seeking all relevant obtainable data that could distinguish between plausible alternative possibilities.
4. Forensic scientists should strive to be free from any conflict of interest. They should possess an independence that would protect their objectivity. Any potential conflict of interest should be disclosed. Work on relevant cases should be avoided or discontinued if objectivity may be compromised.
5. Forensic scientists should undertake cases and give opinion only in their areas of expertise, attained through education, training, and experience.
6. Forensic scientists should attempt to identify, deter, and help eliminate unethical behavior by other forensic scientists through methods such as discussion with a colleague, education, and if unsuccessful, by filing an ethics complaint.
7. It is essential to recognize that honest differences of opinion exist and do not imply unethical behavior by either expert. The legal adversary system includes opposing attorneys seeking out experts with favorable opinions. Forensic scientists should not be blamed unfairly for unpopular verdicts, honest differences of opinion, or the vagaries of the legal system.

8. Passions against an opposing disagreeing expert, or personal animosity, should not constitute the basis for an ethics complaint. Ethics complaints must be made in good faith. If based on passion alone, such ethics complaints themselves are inappropriate.
9. Forensic scientists should present their opinions to the trier of fact in concise understandable language, but care must be taken since such efforts can result in oversimplification and loss of some precision. In their efforts to communicate effectively, forensic scientists should strive to be as accurate as possible and avoid distortion. Every reasonable effort should be made to ensure that others (including attorneys) do not distort the forensic scientist's opinion.
10. Forensic scientists should strive to instill the highest ethical and scientific standards in their students and colleagues through such means as teaching, supervision, setting a good example, publications, and presentations at meetings.
11. Forensic scientists should strive for excellence and the highest degree of integrity. Forensic opinions should not be based on undisciplined bias, personal advantage, or a desire to please an employer or an attorney.
12. When forensic scientists are asked to express opinion on a legal issue, they should make every effort to become familiar with the applicable legal criteria in the pertinent jurisdiction. They should take care to reach only those legal conclusions that result from proper application of the data to that legal issue.
13. Unlike attorneys, forensic scientists are not adversaries. They take an oath in court to tell the whole truth. They should make every effort to uphold that oath.
14. When a forensic scientist accepts any privileged information from an attorney, care should be taken to ensure that all such information is kept confidential and does not reach the opposing side. After accepting such information, forensic scientists should not provide their services to the opposing side unless legally ordered to do so. Forensic scientists should alert attorneys not to make payment or provide privileged information, if they wish to retain the option to be employed by the opposing side.

Ethical Problems in the Forensic Sciences

Some forensic scientists confuse their role with that of an attorney. The attorney's role is to present the best one-sided case for his/her client, the only exception being not to argue for anything, the attorney knows to be untrue. Unlike an expert witness, attorneys take no oath in court. In contrast, forensic scientists take an oath 'to tell the truth, the whole truth, and nothing but the truth'. If forensic scientists assume the attorney's total advocacy role and present the best one-sided case for the retaining attorney regardless of the 'truth' and the oath taken, the forensic experts may be perceived as 'hired guns'. They thereby vilify not only their own reputation, but also taint that of the entire field. Many forensic scientists consider the 'hired gun' problem the most serious ethical problem in forensic science.

A 'hired gun' can establish a track record of testifying for both the plaintiff (prosecution) and defense, depending on the side that hires the expert. An effective 'hired gun' can appear

impartial and objective by giving one-sided misleading persuasive explanations for whichever side hires him/her for a particular case. 'Hired guns' not only always make the best case for the side hiring them, but alternatively they could also do so for a side for which they have a personal bias, regardless of which side they actually believe is right. In contrast, it is possible to have a bias and preferentially work for one side, yet refuse to take on a case unless the forensic scientist honestly believes an opinion is true with the greatest objectivity possible. The distinction between a hired gun and an expert with an idiosyncratic opinion is not always clear-cut without knowing what is in the mind of the expert. Even if experts firmly believe an opinion because of personal bias so that they honestly may be telling what they believe to be true, others frequently might incorrectly view the opinion as a dishonest distortion of the truth. Sometimes, the problem is an insufficient effort by the expert to be objective, or an honest difference of opinion between forensic scientists.

Honest differences of opinion do exist as they do in every science and profession including law, and it is unfair to blame forensic scientists and forensic science for the battle of the 'experts'. Additionally, once a forensic scientist reaches an honest objective opinion, the pressures of our adversary system encourage experts to advocate for their opinion. It is difficult to remain totally objective when defending an opinion. Subtle pressures can also bias an expert, such as the wish to please an attorney or an employer. An honest expert should make every effort to form opinion based on the evidence, even if contrary to the wishes of the hiring person or institution. There are also questions about what it means to tell the truth, the whole truth, and nothing but the truth. Does it mean the expert should try to offer the whole truth and not a misleading part of the truth to the degree that the attorneys and the court will permit? Or is it enough to present only that part of the truth that will help the case and rely on good cross-examination (which may not happen especially if the case is settled before trial) to bring out the rest of the truth? Or should some portions of the truth that may lead to conclusions contrary to the expert's opinion be presented solely as a tactical maneuver to make a pre-emptive strike so that those aspects can be debunked before the other side has a chance to present them?

Should a forensic scientist try to participate in the legal system only in ways that further justice or should the forensic scientist solely answer the questions asked and trust the adversarial system to usually achieve justice? The adversarial approach exists in those countries like the United States that base their system on English common law. Should forensic scientists lend their expertise to sides trying to achieve an 'unjust' outcome? Is it presumptuous for forensic scientists to try to further only what they see as justice or what is consistent with their professional scientific or personal values? Answers to these questions presently lack a consensus and a resolution does not seem likely in the foreseeable future.

Foundations of Ethics

Are ethical guidelines arbitrary rules, or are they based on something more basic and fundamental? Ethical codes address 'important' issues, and seem to represent more than codes of

conduct or codes of etiquette. Sometimes codes confuse etiquette (such as not criticizing another scientist or professional or not hurting an organization) with fundamental ethical issues. There are questions whether any ethical truth is objectively right or wrong, or whether all ethics is subjective and one code is as good as another. Some, who view ethics as subjective, see it as solely dependent on the mores of a specific culture or scientific discipline. They believe that what is considered ethical is only what is morally right to individuals, in that culture or group.

Some consider that the only foundation for ethics and morals is religion. However, religion itself lacks objectivity not only within the confines of a single religion, but also because there would be no consensus as to which of the many different religions should be the standard bearer. Some religions in the past have advocated human sacrifice. Did that make it 'right' for them? There is a long tradition of secular ethics independent of religion in western democratic countries. Although religion can be a basis for ethics, many religiously observant people can be unethical and do 'wrong' things despite engaging in religious practice. Atheists can be very ethical and committed to philosophical study to determine what is 'right'. Although religion can undoubtedly motivate many people to do what is 'right', by no means is religion a necessary foundation for ethics and morals.

Two primary schools of thought exist regarding the basis for ethics. One is consequentialist and proposes that the ethical thing is whatever leads to the best consequences, such as the most good or happiness for the most people. A subset of this position is utilitarianism, insofar as what is most useful is ethical. Another school is deontological and bases ethics on an intrinsic duty. Actions are intrinsically right or wrong regardless of consequences. An example of the latter is the philosopher Immanuel Kant's categorical imperative – to do what you believe any ethical person in your position should do, such that the maxim you are following should be a universal principle for all to follow.

There can be problems with following any of these positions too rigidly. You might consider justice an intrinsic deontological duty, much as Kant did. Does that mean though that every crime no matter how small should be investigated until the perpetrator is punished? It takes consequentialist considerations to balance this duty with the desirability of spending government money on other things that might be more important for society's welfare. Investigating every crime thoroughly until the criminal is caught would use up all our society's resources. No funds would be left for other desirable purposes. Additionally, if deontological considerations were primary, two deontological duties might conflict without any principle to resolve the conflict.

Similarly, following only consequentialist considerations result in problems. For example, it might decrease crime in society if it were perceived that every criminal was always swiftly caught and punished and no criminal ever got away with a crime. To achieve this end it might help to choose individuals from an unpopular group such as prior offenders, try them in secret, find them guilty, and execute them quickly and publicly. Such a procedure might in fact have some deterrent value and decrease crime especially if it were used for white-collar crimes like embezzling money or income tax

fraud. However, deontological considerations of justice convince us that there is something wrong with this procedure. There are even contrary consequentialist considerations. Government could become very powerful, and any of us could be arbitrarily tried, convicted, and executed even if we were innocent. All of us would be at potential risk. Thus, a purely consequentialist foundation for ethics would also provide no way to decide between these competing consequences to determine the right action.

The best approach requires a consideration of both types of ethical foundations, but there is no higher order rule to help us in balancing these considerations. The theoretical approach to resolving ethical dilemmas essentially uses universal ethical principles as 'axioms' from which particular ethical judgments are deduced as 'theorems'. A solution to a problem in a particular case is deduced from the ethical principle. However, there usually is no higher order ethical rule or principle to help us decide among competing ethical principles.

In contrast, the practical approach, known philosophically as 'casuistry', does not involve universal theoretical principles and rules but require us to consider the issues from the perspective of a particular case. General ethical principles and rules essentially are 'maxims' that can be fully understood only in terms of paradigmatic cases that define their meaning and force. However, there can be and often are, differences of opinion about which facets of a case should be overriding, with no ethical guidance to help us in weighing and balancing competing ethical maxims.

In both instances, deontological and consequential considerations can assist us in determining what is 'right'. However, when ethical rules and principles conflict, there generally is no rule, principle, or maxim to help us resolve the conflict. Therefore, it is essential that forensic scientists are able and prepared to think through and resolve ethical dilemmas themselves. In difficult situations, more than one solution usually should be considered acceptable, and ethics committees should not place sanctions on forensic scientists for following either course. In order to help reach the 'best' solution in such cases, consultation should often be obtained from experienced forensic scientists, knowledgeable about ethics issues.

Ethical Dilemmas

Ethical dilemmas often defy consensus solutions. When ethical responsibilities conflict, some forensic scientists always give the legal needs, a priority. The majority, however, usually give the legal needs, a priority, but make exceptions if the law desires an action that violates serious aspects of the values and ethics of their own scientific discipline or profession. In such situations, their professional or scientific values, ethics, and responsibilities may outweigh the desires of the legal system, and preclude their involvement in that aspect of a legal case. Personal ethics and morals can also preclude such involvement. Although the legal system can establish legal ethics, only scientific, professional, and forensic science disciplines and organizations can establish forensic science ethics. The law cannot determine what is ethical in forensic science; it only can determine what is legal.

Ethical dilemmas occur when there are conflicting ethical duties. An example of such a conflict occurs in forensic psychiatry, in circumstances in which a practitioner might sometimes believe that the most accurate and truthful assessment would be attained by misleading the person being evaluated. Such deception is often legal, but it violates forensic psychiatric ethics as promulgated by the American Academy of Psychiatry and the Law. Most forensic psychiatrists follow the guideline of the forensic psychiatric profession, regardless of the frequent legality of such deception. In another instance, many consider the presentation of aggravating circumstances in a death penalty phase of a trial, a violation of medical ethics, even if such aggravating circumstances are true and such testimony in the United States violates no current ethical requirement. The same is true if individuals incompetent to be executed are treated to make them competent. These problems occur when medical or psychological skills are used to evaluate an individual for forensic purposes.

The specter of ethical conflict, however, is by no means limited to forensic psychiatry and psychology or other branches of forensic medicine, but it occurs in all forensic sciences. The use of DNA evidence in the courtroom, although seemingly based on sophisticated modern scientific techniques, with unusually high levels of reliability and certainty, is another example of a highly controversial area. Problems in other aspects such as data collection can be questioned. In many ways it seems counterintuitive that there can be such divergence in professional opinion when accurate data such as DNA evidence are introduced. Nonetheless, controversy does exist about the interpretation of DNA data among highly respected forensic scientists, such as in the widely publicized criminal trial of O.J. Simpson. Does that necessarily mean that one side is unethical or is it possible for honest forensic scientists to hold strong opposing views? One possible explanation is that the highly accurate nature of DNA evidence has made many problems more significant. Potential ethical and data collection problems that had been readily ignored when identification methods were less accurate, suddenly have begun to loom in importance. Many such controversies exist in all forensic science disciplines.

Conclusion

Although the ethical course of action is clear in the majority of situations, it is essential for the 'good' forensic scientist to be knowledgeable about ethics in order to be able to resolve ethical dilemmas when difficult situations arise. It is essential to know the minimal requirements in a code of ethics in order to stay out of trouble and avoid sanctions. However, such codes do not and cannot address all contingencies since differing requirements as well as aspirational standards may conflict. Generally, there is no higher order rule telling us how to resolve such a conflict. In such instances, sometimes with knowledgeable help, forensic scientists must work out their own ethical solutions. Such dilemmas are likely to occur when different disciplines with differing ethics and values intersect, like science and law, in forensic science practice.

Various organizations address different issues in their codes. Two minimal standards for forensic scientists are the

need to be clear and truthful, and not to distort credentials and data. However, the good forensic scientist should strive for more than just staying out of trouble and meeting minimum standards. 'Good' forensic scientists should strive for excellence, both in their ethics and in their forensic science work.

Ethical complexity in the forensic sciences is not a reason to avoid forensic practice. Forensic scientists should accept the challenge, but should be prepared to confront and assess potential ethical conflicts. Myriad problems beset all disciplines, especially those that interface with two very different disciplines like science and law. Forensic science is an interesting, stimulating, and productive vital occupation, but it is necessary to become informed about as many facets as possible in order to become a good ethical practitioner. In most cases, despite the potential ethical dilemmas that have been enumerated, the forensic science codes of ethics provide the required minimal ethics solutions. Those wishing to be good forensic science practitioners who strive for excellence, generally can find guidance in standards of good forensic practice. It is only in relatively rare cases that ethical standards conflict or there are conflicts between provisions in the standards of good forensic practice. In such instances, forensic scientists should be prepared, perhaps with consultation, to perform their own ethical analyses.

Glossary

Green papers Government reports on policy issues.

h-Index A measure of the productivity and effect of a scientist's publications. The index is based on the scientist's most cited articles and the number of times they are cited in other publications.

Impact factor A measure of a journal's prestige, calculated by the number of articles citing articles published in a journal.

White papers Government reports of an informative nature.

Introduction

In a recent law review publication, a group of forensic and legal experts called for greater support in the creation and sustenance of a research culture in forensic science. The authors called for forensic science to focus more on science than on law and develop more of a research, science-based orientation, rather than a quasi-adversarial, legal perspective. This lack of a research culture is not forensic scientists' fault, but rather it results from a lack of research funding and the fact that the main consumers of forensic scientists' work product are associated with law enforcement: prosecutors, police, and the courts. The lack of funding, combined with a general low level of resources in overworked laboratories, made research by operational forensic scientists a low priority. Moreover, until recently, practitioners may not have had the background skills to develop research projects or programs even if there had been institutional funding and support. Research is central to any science enterprise, including forensic science. Case reports and examples should not be mistaken for structured research or empirical data; even if they are published, case reports and accumulated experience, while perhaps instructive to a point, do not go beyond the anecdotal and do not constitute research.

Forensic science research should be funded in proportion to its importance to public safety; currently, it is not. It should embrace an empirical approach, be transparent in its methodology, and cultivate a professional critical perspective.

Research

Scientific research (the word comes from the Middle French *recerche*, meaning 'to go about seeking'; the earliest recorded usage was in 1577) is the process and outcome of applying the scientific method to one or more questions about the world. Research thus provides data, theories, interpretation, and conclusions to help explain the natural and social worlds. In an attempt to move US scientific work forward, Vannevar Bush, a significant and influential scientist, offered the dichotomy of 'basic' and 'applied' sciences in a report to then President Truman.

Much of the scientific research done by government agencies is intermediate in character between the two types of work commonly referred to as basic and applied research. Almost all government scientific work has ultimate practical objectives but, in many fields of broad national concern, it commonly involves long-term investigation of a fundamental nature. Generally speaking, the scientific agencies of the government are not so concerned with immediate practical objectives as are the laboratories of industry nor, on the other hand, are they as free to explore any natural phenomena without regard to possible economic applications as are the educational and private research institutions. (*Science The Endless Frontier*, A Report to the President by Vannevar Bush, Director of the Office of Scientific Research and Development, July 1945)

In time, this distinction was recognized as artificial and the line between what is 'basic' and what is 'applied' science has become blurred (see Stokes' book for a comprehensive argument to this effect). Scientific research typically requires resources; funding for research comes from public agencies, from nonprofit organizations, or by private entities; the latter is particularly true of industrial research. Research resources – that is, funding – are usually awarded through a process of solicitation, review, and selection of suitable and relevant proposals. This key process is often not explicitly taught in university coursework, although some exposure may occur at the graduate or postgraduate levels. A proposal is essentially a fact-based argument with a project plan and budget attached, highlighting requested resources, timelines, and achievements, connecting how the requested resources will be put to use to achieve the stated goals. Formats for proposals vary by funding source; although they pertain to their own formats, most funding sources offer guides to writing proposals, like the National Science Foundation.

Research typically happens in a series of steps; while this may be the case, the creative process necessary to spark a research project or agenda can happen at nearly any time or place. The typical formal steps to research are

- Observations
- Statement of question: hypothesis
- Identification of data sources
- Determination of methods
- Data collection
- Data analysis
- Review of results: interpretation

- Draw conclusion(s)
- Revise any of the previous steps and repeat

Hypotheses are never proved despite what the above process may suggest. If the outcome of one or more experiments refutes the hypothesis, then that hypothesis is rejected. Should the results appear consistent with the hypothesis, however, the results support the hypothesis to some degree. The more the results, and the more the results obtained by various research approaches that support the hypothesis, the more the confidence science has in the strength of that statement. The inability to prove a hypothesis comes in part from the fact that it is impossible to test a hypothesis in isolation – numerous and necessary background assumptions are deeply embedded in any one hypothesis. Scientific research is always testing assemblages of hypothesis at a time; therefore, results that support a hypothesis could be because of any of the background assumptions and not necessarily the hypothesis itself. Conversely, disproving what appears to be one hypothesis could actually be because of one of the background assumptions not holding true under the experimental conditions. Falsification, as a type of negative research result, thus is stronger in that the researcher knows that *something about* the hypothesis did not hold true. A revised hypothesis is required or possibly a deeper investigation of one or more background assumptions is called for.

The goal of research is to produce new knowledge, either positive or negative. Negative results are seen as less useful by some researchers, but this belies the value of knowing what has not worked; not pursuing a particular research path could save time and money. Research can be categorized into two types: primary, where previously nonexistent data are generated and evaluated, and secondary, which summarizes or synthesizes existing data, research, or information. Much like ‘basic’ and ‘applied,’ primary research is often valued over secondary research, although given the amount of information available to modern scientists, it would seem that research that combines or distills new information from existing information (i.e., secondary research) would be just as helpful.

Conducting research is all well and good, but one of the main aspects that provides science with its strength and power to understand the world is to communicate research results to other scientists. Communicating research allows others to review, repeat, and remark on particular research; ultimately, this is a quality check on scientific work to ensure against mistakes, misunderstandings, and outright fraud. To paraphrase Malinowski, science is public, magic is private. The two main methods of communicating research results is through presenting them to audiences at meetings or conferences and to publish them in some form of literature, such as journal articles or books. Presentations at conferences are considered important and timely but ephemeral; while it is a good way for a scientist to stay current in a field, the information is ‘lost’ unless the scientist attends that meeting. Publication is, therefore, the *sine qua non* of research results, available to anyone who finds the information in a library or on the Internet, regardless of where he/she is. The first issue (4 November 1869) of one of the most prestigious science journals, *Nature*, is still available in libraries and even on the Internet. In many ways, research and publication are one and the same.

Publication

Research or academic publishing is the process and industry that communicates the work of scholars to others for peer review and dissemination through print or electronic formats. Disaggregated and idiosyncratic, the process varies widely by publisher, academic field, and medium. Most research is published as journal articles or books. Most journals vary by the field they represent or by topic; ultimately, most academic journals end up being somewhat interdisciplinary because of the number of authors, readers, and cost of production. Journals may be published in print form, in electronic form, or both. Most journals are segmented into at least years and volumes for ease of searching; some may also break the volumes into issues with numbers (Volume 12, Issue 4). Journals may be subscribed to or individual articles may be found at libraries, copied there or purchased (downloaded) via the Internet.

The Publication Process

The process of publication can be thought of in three phases: submission, review, and editing. First, the author has to prepare a manuscript along with any supplementary materials, such as figures (photographs or charts) and tables. The format of the manuscript must conform to the format required by the journal. Once an author has submitted a manuscript to one journal, it is considered unethical to submit the same material to another journal until and unless the first journal rejects the work.

Once submitted, the manuscript is reviewed for content by those who are considered to be the author’s peers, that is, experts in the same field who would understand the questions, methods, and results provided. Peer review is a central concept for academic publishing and acts as a formal quality control process. Experts and scholars who are familiar with the topic of the manuscript typically need to ensure the following for it to be published:

- the work must be accurate and complete;
- the methods must be transparent and repeatable;
- the data must lead to the results offered and the interpretation must be valid, given the data;
- the research and manuscript must be of sufficient merit to justify publication;
- the work must be original and unpublished.

Plagiarism (from the Latin for ‘kidnapping’) is the presentation of another’s work as one’s own; peer review guards against this but outright fabrication can be difficult to detect through the review process. Publications that lack peer review, like most Internet or Web pages, are considered to be unacceptable as proper contributions to a body of literature. Books and book chapters are also considered to be of a lesser quality than journal literature for this same reason: rarely are books reviewed prior to publication with the rigor with which journal articles are. Peer review is critical to establishing a valid, legitimate, and reliable body of research and information. Journal editors will typically seek two to three reviewers out, who independently read a manuscript and make comments,

suggestions, and corrections. The identity of the reviewers is often not disclosed to the author(s) and, likewise, the reviewers may not know who the author is; this process promotes objectivity in the review and commentary. On the basis of the reviews, the editor may accept the manuscript outright, accept it with the provision that the changes suggested by the reviewers are made, or reject the paper for publication in that journal.

After peer review, if accepted, the manuscript then goes through the third and final phase of editing and publication. The author will receive preproduction proofs, called galley proofs, of how the article will be laid out according to the journal's page format. At this stage, only very few or very small changes can be made: The production team at the publisher has the entire journal issue laid out and large changes could spell disaster if they affect other articles. Changes are usually limited to grammar, typographical errors, and labeling. Once all changes are submitted, the article then goes to press as an official publication in a journal.

Not all journals are created equal, however. The prestige of a journal is determined by a number of factors, including age, quality of articles, and reputation. One measure of a journal's prestige is its *impact factor*, which is a calculation of the number of articles citing articles published in a journal. Whether this is a good way to measure the prestige of a journal is debatable, but it is nevertheless the current method of assessing it.

Types of Publications

Scientific literature includes the following kinds of publications:

- articles with original data published in scientific journals;
- review articles that summarize or synthesize previously published work;
- conference proceedings and abstracts;
- books written by one or a few coauthors;
- edited books, where individual chapters are written by different authors and the editor(s) sees to it that the book conforms thematically and editorially;
- government reports (often referred to as 'gray literature').

Peer-reviewed journal articles are the predominant publication type and are considered to be primary sources. Each type of publication listed is considered in detail below.

An article containing original data and results is the pinnacle of research publication. Scientific articles have a standardized format, which may vary somewhat between subjects or journals. The main structure of a scientific article is as follows:

- The *title* should be descriptive and make a statement about the article and its results; 'Gunshot residue detection on smooth surfaces after extended outdoor exposure,' is a better title than 'Some aspects of gunshot residue detection.'
- The *names and affiliations* of all authors are specified. Authorship is determined by the amount of effort in the project, generally, with those doing the most work coming first.
- An *abstract* is then provided, which is a short (500+ words) summary of the article, its results, and conclusions. The abstract was created as a sorting tool, because titles can only be so long and provide only so much information.

- The *introduction* should provide the context of the question researched in the article, typically in the form of previous publications and findings. This section provides the rationale for why the researcher pursued this question.
- The *materials and methods* should detail the empirical process and equipment used. This section needs to be presented with sufficient detail so that another scientist could repeat the research and receive the same results.
- The *results* section should detail the data collected and the outcomes of the analysis with appropriate statistical and visual summaries (tables, charts, graphs, spectra, etc.). Each of these *figures* should be titled (the *caption*) and described with accompanying references to the text of the article to which it corresponds.
- The interpretation of the results is offered in a section titled *Discussion* or *Conclusion*. Here, the author(s) pull together all the results of their current work and other relevant literature and make larger statements about the significance of their work. The conclusions should follow logically from the data and results so that the chain of reasoning is clear.
- The last section is a list of references or citations, literature cited in the current article.

The greater the number of original articles a scientist produces, the higher he/she is held in regard by his/her peers. The *h-index* attempts to measure the productivity and effect of a scientist's publications. The index is based on the scientist's most cited articles and the number of times they are cited in other publications. The main journals for publishing in the forensic sciences are listed below (alphabetically):

- *American Journal of Forensic Medicine and Pathology*
- *Australian Journal of Forensic Sciences*
- *Canadian Society of Forensic Journal*
- *Forensic Science International*
- *Forensic Science Policy and Management*
- *Forensic Science Review*
- *International Journal of Legal Medicine*
- *Journal of Forensic Identification*
- *Journal of Forensic Sciences*
- *Science and Justice*

Other journals, magazines, and newsletters abound but may have little academic-style review or oversight. Review articles summarize the work on one topic or that over a period of time. Some journals, like *Forensic Science Review*, are devoted exclusively to review articles, but most journals publish few if any review articles. A journal or editor may solicit for submissions to a review topic. Review articles are particularly useful for education at the upper division undergraduate or graduate levels. One publication, the *Interpol Forensic Science Manager's Symposium*, provides a 3-year summary by topic in the main areas of forensic science and is produced once every 3 years.

Some conferences or meetings publish either the abstracts or short versions of the presented work. Although typically viewed as a lesser form of publication, in some instances it may be the only form: A recent paper found that the rate of publishing research presented at one conference was at most a third (102 published out of 623 abstracts). This research supports the lack of a mature research culture in the forensic sciences.

Books published by university presses are considered to be of higher prestige than those by commercial publishers. Numerous books are published each year and the extent to which the manuscripts are reviewed varies by publisher, topic, and type of book. The Internet has made publishing books extremely easy, either through traditional channels or via 'vanity presses,' where the author pays to have his/her own work printed.

Government reports, 'Green papers' (policy), 'White papers' (informative), and other types of information generated either directly or through activities funded by a government make up what is sometimes called the 'gray literature.' These publications may be difficult to find because of limited production and distribution; some may even be sensitive or classified and not available for public consumption. Again, the Internet has changed the way government publications are produced and made available: Websites like the National Criminal Justice Reference System, www.dna.gov, the European Network of Forensic Science Institutes, and the Australian National Institute of Forensic Science have made the distribution of forensic publications sponsored by governments easy, cheap, and fast.

Training to Competence

C Welsh and G Aitchison, Skills for Justice, Edinburgh, UK

© 2013 Elsevier Ltd. All rights reserved.

Introduction

The following quote from the Committee on Identifying the Needs of the Forensic Sciences Community, National Research Council's 2009 report 'Strengthening Forensic Science in the United States: A path forward' highlights the importance of a holistic system in which the competence of practitioner, process, and organization is paramount across all forensic disciplines.

The quality of forensic practice in most disciplines varies greatly because of the absence of adequate training and continuing education, rigorous mandatory certification and accreditation programs, adherence to robust performance standards, and effective oversight.

This article explores the concept of competence and how forensic science providers (whether in a police and law enforcement or independent laboratory environment) train and assess practitioners to an agreed industry standard. Key to the training and assessment of practitioners' competence in forensic science is reference to the personnel requirements within the recognized industry standards for the forensic science sector; these are as follows:

ISO/IEC 17025: 2005 (E) for laboratory testing and
ISO/IEC 17020: 1998 (E) for crime scene investigation.

What Is Competence?

There are different definitions of competence; however, the following definition is accepted by the Association of Chief Police Officers, the Forensic Science Society, and other forensic science providers and covers the fundamental principles for competence in UK Forensic Science.

The skills, knowledge, and understanding required to do a role are evidenced consistently over time through performance in the workplace.

This article highlights how nationally recognized standards of competence can be used effectively across forensic science people processes to ensure staff are recruited, trained, developed, promoted, and professionally recognized throughout their career. This is a broad-based definition and shows that occupational competence is more than just the skills required for the job.

Underneath the definition above sit four subsections of categories of skills, knowledge, and understanding:

- Technical competence – The occupational skills and knowledge required to be effective in a specific function and/or role.
- Managing the work process – The ability to manage overall organizational processes such as planning, monitoring quality, and solving problems.

- Working relationships – Managing relationships with internal and external colleagues and customers.
- Managing the work environment – Health and safety, ethics, values, behaviors, and quality.

What Is Training?

The US National Institute of Justice in 2004 defined training as the 'formal, structured process through which a forensic scientist reaches a level of scientific knowledge and expertise required to conduct specific forensic analyses.' This definition is very useful and can refer to the training of any forensic practitioner, not just a forensic scientist.

Staff competence can be achieved through embedding nationally agreed standards of competence across the organization's systems and people processes; however, this article looks in detail at how these standards can be used as a basis for effective design, delivery, and evaluation/assessment of training and learning for staff. Before looking specifically at training, the standards of competence and how they can be used are discussed.

In the United States of America, there are a suite of Scientific Working Groups established by practitioners to establish relevant standards for their relevant forensic areas such as Scientific Working Group for the Analysis of Drugs (SWGDRUG), Scientific Working Group on Bloodstain Pattern Analysis (SWGSTAIN), and Scientific Working Group on Digital Evidence (SWGDE). Each of these SWGs set some standards and expectations around the training of the practitioners in their respective areas.

What Are Standards of Competence?

Standards of competence, in relation to personnel in an organization, are developed to define key activities that make up the functions and roles of an organization and usually wider than this, a sector. These standards define what is required in relation to the skills, knowledge, and understanding for staff to perform effectively and consistently. Standards of competence in relation to personnel can complement and align with other standards and benchmarks and together can define overall organizational competence in relation to systems, processes, and people, bringing benefits such as standardization, consistency, transferability, and benchmarking of good practice across organizations, regions, and countries.

Such standards become vitally important when states exchange forensic test results and other types of evidence while prosecuting cross-border crime.

In the UK, National Occupational Standards (NOS) are the nationally agreed standards of competence that not only

define organizational people competence but also provide a benchmark across other organizations with similar functions and roles. Standards of competence define occupational competence and staff who are regularly assessed to these standards will be competent and capable and able to consistently demonstrate the skills, knowledge, and understanding required for their role.

When organizations use standards of competence effectively, they can be confident that their workforce is achieving agreed standards developed for, and aspired to, by other practitioners and organizations in their sector/industry. Using competence standards with other industry standards (such as ISO/IEC 17025: 2005 (E)) creates a joint process for overall organizational competence in relation to systems, processes, and people.

In 2004, the European Network of Forensic Science Institutes published a set of 'performance-based standards for forensic practitioners.' These were based on the NOS developed by the Science UK Sector Skills Council, SEMTA, in the early 2000s. So internationally recognized competence standards for forensic practitioners do exist.

What we hope to illustrate is how to train and assess an individual as competent against a globally applicable codification of what a forensic science practitioner needs to know, understand, and do.

What Should a Standard of Competence Do?

Standards of competence must describe competent performance in terms of outcomes of an individual's work and the skills, knowledge, and understanding they need to perform effectively and consistently. They allow for clear assessment of competence and should be nationally agreed, developed for a sector, through consultation with employers in that sector across a range of workplace activities, and the different circumstances these activities require for a role. In this way, defining outcomes rather than the steps taken to achieve the outcome provides the necessary flexibility to meet the needs of individuals.

How Are National Standards of Competence Developed?

In the UK, the development of such standards is employer led and is based on collaborative working across a vocational sector. Steering groups and working groups made up of experts and key practitioners from within each sector work together to develop and agree the standards.

What Should Standards of Competence Look Like?

Standards of competence are made up of statements of competence and are broken down into performance (what someone needs to do), knowledge, and understanding criteria (what someone needs to know and understand to be able to achieve the performance criteria), and each standard will define a key part of a role.

Each standard will have an overarching summary, which details the following:

- how it links to other standards (this makes it easier to group standards together to define overall competence for specific roles).
- what the standard is about (linked to a specific function);
- who the standard is aimed at (linked to a specific role or level of employee);

By grouping together standards, you can specify the full range of skills, knowledge, and understanding for any role in an organization. Standards can be divided into different elements, which further define key activities within a role.

Standards of competence often include a range of circumstances and situations that are important to achieving overall competence in an activity. These can help individuals prepare for the different contexts or contingencies they could face and can help line managers to measure when someone is fully competent in their role.

How Can Competence Standards be Used?

In a nutshell, standards of competence can be used right across all people processes, providing staff with a relevant, transparent framework for competence and continuous learning and development throughout their career and when combined/aligned with other standards such as ISO/IEC 17025: 2005 (E) provide excellent frameworks for organizational competence.

As long as the requirements for competence within each standard can be evidenced, organizations can put in additional measures to suit their internal needs. The important thing to remember is any additional measures that need to be relevant and measurable for staff and the organization and should not alter the intended outcomes of the standard. Each organizational standard operating procedure or validated scientific method will map directly to a performance criterion within the standard easing assessment of the individual as the practitioner must only follow the organizations' processes to meet the required standard.

Training to Competence

Some employers have told the authors that they believe only around 60% of the content of training and development programs/interventions they use are relevant to those attending, meaning that they are spending money and resources where they do not have to.

Training to competence will mean different things to different organizations, and the Scientific Working Groups in the United States have developed useful guidance in this area.

SWGDRUG states that all new analysts shall have at least a bachelor's degree or equivalent (generally, a 3–4 year post-secondary degree) in a natural/physical science. Coursework shall include lecture and associated laboratory classes in general, organic, and analytical chemistry. SWGDRUG goes on to state that in terms of initial training requirements that there shall be a documented training program, approved by laboratory management that focuses on the development of theoretical and practical knowledge, skills, and abilities necessary to examine seized drug samples and related materials. The training program shall include documented standards of performance and assessment plan to check understanding of key points; a training syllabus detailing required knowledge

and skills in specific topic areas; a period of supervision of practitioners; and a verification document.

SWGSTAIN requires a minimum of a bachelor's degree or equivalent in the field of study relevant to blood pattern analysis (BPA) from an accredited university or college, associate's degree or equivalent in a field of study related to BPA from an accredited college or university, or a high-school diploma and 4 years job-related experience. SWGSTAIN also sets requirements for competency training, which states that a BPA trainee must participate in and successfully complete a competency test before performing independent analysis and rendering expert opinion. Competency testing may be administered incrementally and/or cumulatively to allow the trainee to conduct some of the analyses independently.

SWGDE set out that all personnel shall receive necessary training and be qualified for assigned work. Each category of testing shall have a documented training program for forensic technical personnel. The training program shall provide for maintaining the skills and expertise of personnel and provide for retraining, when needed. The training program shall cover the technical and administrative aspects of the job. For examiners, the training program shall also include training in the presentation of evidence in court. For examiners, the training program shall include the application of ethical practices in forensic sciences, a general knowledge of forensic science, courtroom testimony, and applicable criminal and civil law and procedures.

However, in forensic science, where competence can be called into question in court and is regularly under scrutiny, it is vital that organizations have simple, measurable standards of competence that form the basis of training and development across the organization.

Standards of competence can provide an overarching framework in which all recruitment, job descriptions, training, and assessment of staff align. The section 'Training to Competence,' highlights how SOPs can map to the statements of knowledge, skills, and understanding detailed in each standard.

If this is taken as the starting point, a role description can be created based on the function that any individual may carry out, for example, a Crime Scene Investigator or CSI. A CSI performs the function of collecting evidence from the locus of a crime and transferring it to a laboratory to allow examinations and tests to be carried out on these items, if appropriate.

This role description will contain perhaps four or five standards of competence, which state what outcomes competent performance of this function will achieve.

Concurrently, there will exist a series of SOPs that set out in detail how the CSI will achieve the outcome. For example, the outcome is as follows:

- Handle, package, seal, label, and record items and samples correctly, and in a manner that prevents contamination, cross-contamination, loss, or degradation of potential evidence.
- There will be a series of SOPs that will exist, and if followed, will result in that outcome being achieved.

Once all the SOPs that will achieve all the outcomes of competent performance as set out in the standards of competence have been identified, you have clear training outcomes for the CSI.

The employer needs to train the CSI in the SOPs identified, which will achieve the outcome as set out in the standard of competence (which in turn is linked to the CSI job description).

By linking standards of competence and their performance criteria to SOPs, you can efficiently and effectively train an individual to be competent to perform the SOPs, therefore meeting agreed standards of competence linked directly to their role, and aligned to the function that the individual is to carry out.

In summary, to train an individual to competence:

- identify what function a role is to perform;
- decide the key outcomes the role must achieve;
- link SOPs to the role that, if followed, will result in such outcomes being delivered;
- train the individuals in that role to be able to perform the SOPs while learning the underpinning knowledge and understanding; and
- assess the ability of the individual to perform the SOP/ explain the underpinning knowledge.

The most effective way to achieve this is to have nationally or internationally agreed standards of competence, which set out what the outcomes of competent performance are and use this as an overarching framework for the job roles, SOPs, recruitment, training, and assessment of practitioners.

Identifying a training need using a competence standard

A competence-standard-based job description/role profile will define competence for that role. When someone is not yet competent, the gap between where they are now and where they need to be should be clear. The performance and/or knowledge criteria and any range statements (the different circumstances/contexts that make up overall competence for this standard) can be used as the basis for developing relevant, measurable training.

Writing learning outcomes using standards of competence

When a training need or gap in competence is identified, you can identify what it is you need individuals in a role to be able to do skills and know (knowledge and understanding) as a result of the training. A standard-based training outcome will be written in a way that clearly shows this and is able to be assessed.

Measurable standard-based training outcomes will include 'performance' criteria for practical elements of any training and 'knowledge and understanding' criteria for the theoretical element. As standards of competence are written as outcomes, the criteria within them can often be used directly as individual training outcomes. As long as the outcomes are achievable and measurable for those attending the training, they will be effective.

That is, an outcome will state what the individual will be able to do once they have been taught the relevant SOPs.

Delivering training based on standards of competence

Delivery must be appropriate to meet training outcomes. For example, performance-based outcomes will be best achieved through interactive, trainer led interventions or in 1:1 coaching

where there is opportunity for practical application and an opportunity for this application to be observed and assessed by a competent person.

Similarly, knowledge outcomes are best achieved (unless explicit in practical exercises) through interventions that include an individual knowledge check/assessment as part of or at the end of the training; for example, online learning programs/e-learning.

How to assess standard-based training outcomes

Assessing skills, knowledge, and understanding against standards of competence requires occupational competence, and for an area such as forensic science, this is particularly important. Business critical training should be delivered by experienced practitioners. A good understanding of standards of competence is required and organizations using these standards must ensure all staff involved in people processes come together to understand how these work and more importantly how they will benefit the organization.

The most common methods of assessing training are as follows:

- practical exercises that allow for all individuals to demonstrate the required skills, observed by a competent person who understands the required standards,
- written work such as knowledge checks and written assessment questions, and
- project work that can go beyond the training where individuals have to undertake a piece of work that requires them to evidence the meeting of all the required standards.

Using standards of competence to design, deliver, and assess training provides managers with confidence that their staff are attending training that is relevant and meaningful for their role. This will also benefit organizations through reducing the amount of time and resources required for training, allowing targeted training that focuses on the specific needs of individuals and their roles. At a time where training budgets are declining, organizations should think about standards of competence to address this.

All these methods can assess the performance of the relevant SOPs and the associated underpinning knowledge and understanding in the workplace, which is essential to ensuring the competence of the practitioner.

How Can You Measure Ongoing Competence?

Standards of competence also form the basis of vocational qualifications that are developed by grouping together relevant standards that (when assessed together) show that someone can carry out a job/role to the required standard. To achieve a nationally recognized qualification, candidates need to provide current, sufficient, and valid evidence from their own work to demonstrate that they have covered all the criteria and the range (the different circumstances or situations in which the task might be carried out) within each standard that makes up the qualification.

Vocational qualifications should be assessed by occupationally competent assessors. This is what gives these qualifications

credibility and authenticity both inside organizations and across the sector.

It is becoming common for forensic science providers to rely on ISO/IEC 17025: 2005 (E) to assure staff competence; however, this standard does not go far enough into individual competence and the approach to combine ISO/IEC 17025: 2005 (E) with nationally agreed competence standards such as the approach the England and Wales Forensic Science Regulator has advocated in his draft Code of Practice stating:

The provider should utilize available NOS produced by Skills for Justice for determining the appropriate competence framework for technical roles.

Vocational qualifications can be a valuable addition to career pathways within an organization and can provide evidence for the recruitment process, widening the talent pool for internal and external recruitment.

In the definition of competence that has been used throughout this article, one of the key points is that competence must be shown over time. It is not a one off event. Achieving a qualification in anything only shows that a practitioner was competent at that time. It cannot be a passport to a career with no further assessment of competence, further training or further professional development. A qualification is not a veil to hide behind to avoid demonstrable continual improvement.

The following framework of assessing practitioners as competent in the workplace within an accredited quality management system without the need for a qualification is a very useful tool.

In developing this Competence Assessment Framework for Scientific Support (UK), Skills for Justice recommends the following methods for assessing competence:

- Observation – where a competent practitioner sees the required level of performance in a real work situation.
- Witness testimony – this is where a competent practitioner will verify that they have seen the required level of performance by the individual in a real work situation.
- Product evidence – this is where written work can be offered as evidence of an individual meeting requirements of a standard (e.g., reports written, feedback received from colleagues or customers).
- Simulation – in certain situations, it may not be possible to provide evidence of all standards (due to lack of opportunity in some specialized roles). In these cases, it is acceptable for simulated situations to be developed to show how someone would perform. This should only be used when there is no possible work-based opportunity.
- Professional discussion – this is where an individual has a detailed discussion about their work with a line manager or a qualified assessor who can use this information to evidence the standards required.

National Academy of Sciences (NAS)

SA Cole, University of California, Irvine, CA, USA

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Conflict of interest (COI) Bias, or the appearance of bias, because an individual with decision-making power has an interest, usually financial, that may be affected by that decision. Defined by the NRC as “any financial or other interest which conflicts with the service of the individual (on a committee) because it (1) could significantly impair the individual’s objectivity or (2) could create an unfair competitive advantage for any person or organization.”

National Academies (NA) Umbrella term for the National Academy of Sciences and its sister institutions, the National Academy of Engineering and the Institute of Medicine.

National Academies Press (NAP) The publishing arm of the National Academies.

National Academy of Sciences (NAS) 150-Year-old honorific society composed of distinguished scientists.

National Research Council (NRC) The operating arm of the National Academies.

Introduction

The United States National Academy of Sciences (NAS) is “an honorific society of distinguished scholars engaged in scientific and engineering research, dedicated to the furtherance of science and technology and to their use for the general welfare.”

The NAS was established by the US Congress in 1863 during the Lincoln administration with a mandate to “investigate, examine, experiment, and report upon any subject of science or art” whenever called upon to do so by any department of the government. The NAS created the National Research Council (NRC), its operating arm, in 1916, the National Academy of Engineering (NAE) in 1964, and the Institute of Medicine (IOM) in 1970. Recently, these four institutions collectively adopted the name The National Academies (NA).

There are other important and prestigious scientific institutions in the United States with somewhat different mandates, such as the American Academy for the Advancement of Science. However, the NA claims to be “the nation’s premier source of independent, expert advice on scientific, engineering, and medical issues.” It has been called “the most prestigious scientific association in the country.” Few would dispute these characterizations.

The NAS membership is composed of approximately 2150 members and 430 foreign associates, NAE has 2200 members and 203 foreign associates, and IOM has 1700 members and 120 foreign associates. Election to one of the three entities is considered one of the highest honors that can be accorded to scientists, engineers, doctors, and public health scholars and officials.

The NA is located in Washington, DC, headquartered in a historic building built in 1924 near the national mall. It has additional space in the Keck Center of the National Academies, built in 2002, and it also administers the Marian Koshland Science Museum.

The NA has a number of standing committees on various topics pertaining to science, technology, and medicine. Not all committee members are academy members. Standing committees are distinct from committees convened to produce specific reports.

The NA’s activities include convening workshops and conferences, publishing several journals including the prestigious *Proceedings of the National Academy of Sciences*, education and outreach activities, international cooperation, and the bestowing of a number of important awards for scientists and engineers. Perhaps NA’s most visible activity, however, is the NRC’s convening of between 200 and 300 expert committees each year to produce ‘consensus studies’ that are published as reports. Around 6000 experts serve, without pay, on NRC committees each year. Because of the NA’s reputation, NRC reports command a special authority on scientific and technical matters. As one scholar has observed, “No other U.S. institution has the same mix of characteristics: unquestionable scientific and technological expertise; an official congressional charter to provide scientific advice to the federal government; and independence from the political chain of command. NRC reports draw a great deal of credibility from these aspects of the Academy’s identity” (Hilgartner, 2000: p. 45). To be sure, this does not mean that all NRC reports are accepted as representing a ‘consensus’ by either the scientific community or the public. However, the NA works hard to ensure that most of them do.

The NRC uses a standard process for producing reports that is designed to enhance the credibility and integrity of its reports. Its mechanisms for enhancing credibility include soliciting public comment on the committee membership, conducting conflict of interest checks on committee members, and submitting draft reports to external independent peer review.

Relevance to Forensic Science

Given the widespread perception that mainstream science has tended to neglect forensic science, the interest taken by the NA in forensic science since around 1990 may reasonably be viewed as representative of a renewed effort by mainstream scientific institutions to better engage with forensic science. The NA has engaged in a variety of activities related to forensic science, such as devoting a special issue of its magazine *Issues in Science and Technology* to the topic, convening a Sackler

Colloquium, hosting panels on forensic science at its annual meeting, and publishing the *Reference Manual on Scientific Evidence*. However, the primary relevance of the NA to forensic science is through the NRC's well-known and well-regarded process for convening committees of scientists, engineers, health professionals, and other experts to produce 'consensus studies' on scientific and technical matters of national importance.

Controversies over the use of various forensic techniques have arisen periodically. Although controversies are sometimes aired in the usual forums for scientific disagreements, such as the pages of scientific journals and the panels of conferences, many of these controversies find their way into litigation. Courts have some attributes, such as cross-examination, that may be viewed as conducive to the airing of scientific controversies, but they have many other attributes that make them undesirable forums for resolving scientific controversies. These include being confined to specific cases and facts, rather than general issues; the absence of scientific training on the part of courtroom actors like judges, attorneys, and jurors; the polarizing effects of the adversarial system; potential inequities in the resources or legal skills deployed by the two sides; the potential for inconsistent or even conflicting judgments from different courts; the slow pace of the legal process; and so on. Dissatisfaction with the use of litigation as a mechanism for resolving forensic scientific controversies has occasionally prompted various commentators to view the NRC as a sort of 'court of last resort' – indeed, the NAS has been called 'the nation's supreme court of science' – or at least a useful forum, in which to try to resolve forensic scientific controversies. This manner of drawing on a governmental (or, in this case, quasi-governmental) body for science advice may be viewed as consistent with practices in a wide variety of scientific, technical, and medical matters in which science advisory boards are treated as a virtual 'fifth branch' of government. For the above reasons, at least eight of the more than 4000 reports issued by the NRC in its history have directly concerned forensic science:

- [1] On the Theory and Practice of Voice Identification (1979)
- [2] DNA Technology in Forensic Science (1992)
- [3] The Evaluation of Forensic DNA Evidence (1996)
- [4] Forensic Analysis: Weighing Bullet Lead Evidence (2004)
- [5] Ballistic Imaging (2008)
- [6] Strengthening Forensic Science in the United States: A Path Forward (2009)
- [7] Nuclear Forensics: A Capability at Risk (2010)
- [8] Review of the Scientific Approaches Used during the FBI's Investigation of the 2001 Anthrax Letters (2011)

These reports will be referred to by number in the remainder of this article.

In addition, some NRC reports did not focus on forensic matters directly, but were peripherally relevant to forensic issues. These include:

- [9] The Evolving Role of Statistical Assessments as Evidence in the Courts (1989)
- [10] Black and Smokeless Powders: Technologies for Finding Bombs and the Bomb Makers (1998)
- [11] The Polygraph and Lie Detection (2003)

These reports will not be discussed in this article.

Funding

The NA is a private organization with a mandate from the US Congress, not a government agency. It does not fund its own reports, and its budget is almost entirely dependent on contracts to produce its reports. Typical funding sources for NRC reports include federal agencies, state agencies, private foundations, or the NA endowment. Of the forensic reports, three ([1], [4], [8]) were solely funded by the Federal Bureau of Investigation (FBI). For [2], FBI funding was supplemented by funding from four government agencies and a private foundation. These same four agencies, plus the Department of Energy, funded [3]. The reports [5] and [6] were solely funded by the National Institute of Justice (NIJ). An earlier effort to secure funding from the Departments of Justice and Defense (DOD) and a private foundation for a report with a scope quite similar to [6] "was dropped because the government insisted on rights of review that the Academies have, at least in the recent past, refused to grant a sponsor" (Kennedy 2003). Funding for [7] was provided by the Department of Homeland Security, DOD, and the National Nuclear Security Administration.

Rationale for Reports

The usual literary form of an NRC report is to frame it as a response to an official request by some government agency for help, study, or information. It should be noted that the requesting agency is not always the funding agency. Thus, five reports ([1], [2], [3], [4], [8]) were framed as responses to FBI requests. The FBI requests for [1], [2], and [4] referred primarily to legal controversies over the legal admissibility and scientific validity of various techniques. The report [3] was explicitly requested as a response to vociferous criticism of [2], in particular its recommendation of the 'ceiling principle' for reporting the results of DNA associations. The report [8] was unusual in that the FBI asked the NRC to serve as sort of *de facto* peer reviewer of its use of rather cutting edge science in an extremely high profile case in which a trial had been precluded by the suicide of the suspect. The NIJ requested [5] primarily in order to evaluate the feasibility of a national ballistics database. Congress requested [6] with an extremely broad charge to address the 'needs' of the forensic community, needs which included funding, scientific research, education and training, and dissemination of best practices. Three agencies jointly requested [7] with a rather unspecific request for recommendations for improvement.

In addition, to the 'official' request, some NRC reports refer to constituencies other than the requesting agency which may desire NAS intervention. For example, [2] refers to "a crescendo of questions concerning DNA typing" that led to "calls for an examination of the issues by the National Research Council of the National Academy of Sciences ... from the scientific and legal communities."

Finally, of course, there may be reasons for convening NRC committees that are not explicitly stated in the report. For example, it has been asserted that the Consortium of Forensic Science Organizations was instrumental in getting Congress to fund [6], but this is nowhere stated in the report.

Scope

The reports vary widely in scope. The most common type of report is an analysis of a specific, novel forensic technique that is (at the time of the report) emerging into relatively widespread use (e.g., [1], [2], [3]). One report [5] made comments on a forensic technique (toolmark analysis) that were largely incidental to its charge, which was to evaluate the feasibility of a national database. Some reports are still more specific. One report [4] concerned a technique so esoteric that it was used only by a single laboratory in the United States (and only two laboratories in the world), another [8] concerned a technique so specific that it has been used only in a single *case*, and a third [7] concerns a discipline that is largely distinct from the rest of what is generally thought of as 'forensics.' The report [6] differs from the others by seeking to cover 'forensic science' broadly, rather than focusing on a specific technique, and by focusing on longstanding, rather than novel, techniques. Still, this report was not able to cover all of forensic science, and the disciplines most discussed were drug analysis, fingerprints, impression evidence, firearms and toolmarks, hair and fiber analysis, questioned documents, paint, explosives and fire, odontology, bloodstain patterns, digital forensics, and the coroner system.

Composition of Committees

The NRC has a regular process for convening committees that is employed for virtually every committee. The rules governing the process are discussed in a number of documents available on the NRC's website. The NRC seeks committee members who are "highly qualified in terms of knowledge, training, and experience." Names of potential committee members are solicited by NRC staff from NA members, individuals who have served on previous committees, networks of 'contacts and resources,' sponsors of the studies, groups with an interest in the topic, members of the relevant disciplines, and the general public. Committee members need not be Academy members, but NA membership is considered a plus. The NRC insists that committee members serve as individual experts, not as representatives of organizations or interest groups. The NRC strives to achieve both a 'range of expertise' and a 'balance of perspectives' in assembling committees.

Nominees must be approved by several levels of review within the NA including the Chair of the NRC. The provisional list is then posted on the internet and opened for 20 days of public comment. The NRC also has a conflict of interest (COI) screening process that is applied to every committee. An extensive discussion of the NRC's COI policies is available on its website.

The forensic committees were consistent with these guidelines and with NRC committees in general. The forensic committees were composed of between 8 and 22 (mean = 14) members. They mostly consisted of highly credentialed scientists, typically drawn from academia, though some were from industry or government. Some of the forensic committee members have been repeat players, who served on multiple committees. Each committee had Academy members, ranging from 1 to 7 Academy members on each committee. Most, but by no

means all, committee members held doctorates from natural scientific fields. Most of those without doctorates in natural science tended to fall into three categories: (1) individuals with special expertise in forensic science; (2) individuals with expertise in law; and (3) highly credentialed engineers who did not possess doctorates. Each committee had between 1 and 6 members whose expertise derived, in some part, from forensic practice or institutional governance. Each committee had between 1 and 4 members whose expertise lay primarily in law rather than science, based presumably on the reasoning that forensic science is 'science in law' and thus recommendations concerning forensic science would benefit from the expertise about the legal system. Seven of these 'law' members were professors, three were judges, and three were private attorneys.

Additions and Subtractions from Committees

One member was added to [1] partway through the study process. Two members of [2] resigned after defence attorneys and others questioned their objectivity given their ties to commercial DNA profiling vendors, although these individuals had *survived* the NRC's initial COI screening process. One member did not serve a full term on [5]. One member was added late to [6].

Data-Gathering Process

The NRC uses four main methods of gathering information: public hearings, public submission of information, review of scientific literature, and investigations by committee members or staff. Committees are assisted in the research process by NRC staff. For the forensic reports, between 1 and 15 staff members (mean = 6) assisted the committees.

Committee Deliberation

Although many committees hold public hearings, committee deliberations are treated as confidential. The rationale for this is to allow for the candid exchange of ideas among committee members; however, given the weight afforded the NA on scientific matters of national importance, the policy also has an obvious downside in terms of public transparency. In 1997, a United States Court of Appeals ruling held that the meetings and documents of NA committees must be open to the public, like any other government scientific advisory board. However, Congress passed a law shortly thereafter exempting the NAS from these rules, allowing committee deliberations and documents to remain confidential for a period of 25 years.

Dissension Within Committees

The NRC advertises its reports as 'consensus studies,' and it works hard to achieve consensus on all its committees and keep dissension 'backstage.' Such efforts are usually, but not always, successful. When such efforts fail, the veneer of

unanimity is breached through minority reports, resignations or removals, press leaks, public denunciations, and so on. Since many, though by no means all, NRC reports concern *controversial* scientific, technical, or medical issues, many committees are convened with highly interested public groups monitoring their proceedings, alert for any sign of ‘politicization’ of the process.

Most of the forensic NRC committees maintained at least a public face of consensus. The main exception was [2], primarily over the issue of the ceiling principle. An early draft report that espoused a more statistically conservative, defendant-biased approach was leaked to the FBI, prompting angry letters to the NRC. *Science* called it “one of the most contentious [NRC] reports in recent years,” reported “much strife, a threatened minority opinion, and countless leaks of confidential drafts,” but noted “the committee nevertheless achieved what at times seemed an impossible goal: a unanimous report.” However despite the veneer of unanimity, after the release of the report, some committee members seemed to disavow it, in court and elsewhere. For example, one committee member who “was actually the person responsible for writing’ the section in the NRC report dealing with the variation of the product rule known as the ‘ceiling principle,’” testified that it was “a really unbelievably conservative approach, very, very pro-defense approach” producing a “vastly too conservative estimate” (quoted in Kaye, 2010: p. 114).

Peer Review

All NRC reports are peer reviewed. The NRC’s peer review process is overseen by a Report Review Committee composed of NA members. This committee sends the draft report to independent individuals viewed as expert on the subject who were not involved in the committee process. The reviewers comment on and critique that draft. Draft reports are embargoed, and reviewers are asked not to release them. The authors of the report are expected to consider all review comments and to provide written responses, which are evaluated by a ‘monitor’ or ‘review coordinator.’ The report cannot be released until the NA feels that the review process has been satisfactorily completed. NRC report reviewers are *not* anonymous (in the way that peer reviewers for many scholarly journals are), in that their names are eventually published in the report. However, names are never linked to specific comments, and the reviewers remain anonymous *during* the review process.

Primary Findings

NRC reports are long, often book length, documents. Readers’ attention is inevitably focused on their conclusions, which are variously called ‘findings,’ ‘recommendations,’ or ‘conclusions.’ These vary greatly across the reports in number and level of specificity. However, some general observations can be made.

Not surprisingly for reports written by a scientific institution, every report called for more research to be conducted. These calls range from the very specific to the general. Most

reports called for better use of existing knowledge and/or technology. Almost all reports also discussed what we might call the ‘governance’ of forensic procedures. Such recommendations included issues such as certification, accreditation, quality control and assurance, oversight and enforcement, best practices, standards, protocols and rules, and proficiency testing. Most reports offered general recommendations concerning the proper interpretation of forensic results; Reports [2], [3], and [4] recommended specific interpretative rules. Some reports assessed the validity of various forensic claims, while others recommended that attention be paid to validity issues. Recommendations concerning transparency, education and training, and organizational reform were also common. The reports recommended the creation of two new agencies or commissions. Two reports made specific recommendations for ([2]) or against ([5]) the creation of databases. Reports [2] and [7] made recommendations concerning the governance of databases. [2] and [3] recommended equity between government and criminal defendants in terms of access to evidence. Reports [2] and [7] recommended greater international cooperation, and [6] and [7] made recommendations concerning resources allocated for forensic science. The report [2] alone made recommendations concerning privacy issues, and [6] alone made recommendations concerning ethics.

NRC Reports and Legal Issues

Confusion and controversy have sometimes arisen about whether NRC reports do, or should, opine on legal issues, such as proper reporting of conclusions and the admissibility of various forms of forensic evidence. With the exception of [8], which offered clear conclusions about evidence in an individual case, forensic NRC committees have viewed specific cases, past, present, or future, as outside their purview. Most have also viewed general opinions on the admissibility of a specific forensic technique as also outside their purview. This makes sense in that the NRC is scientific, not a legal, institution. Its presumed value is in articulating *for* legal institutions the consensus of the scientific community. Nonetheless, for reports on forensic science, the distinction between evincing an understanding of the legal context of the science and espousing a legal conclusion may sometimes be a fine one. In addition, all of the NRC committees pertaining to forensic science have included members with legal expertise (judges, law professors, and attorneys), including, in one case [6], as Co-Chair. Under these circumstances, the temptation for the committee to opine – or for outsiders to interpret the report as having opined – on legal issues is understandable. Thus, a number of the reports generated debates over whether they should be read as having reached legal conclusions and, if so, what those conclusions were. For example, [2] was initially read by the press and some attorneys as having advocated that DNA evidence should not be admissible until the quality assurance, accreditation, and proficiency testing measures it recommended had been implemented. The committee issued a clarification, stating that a moratorium on the use of DNA evidence was not necessary (thus effectively taking a position *for* legal admissibility). Statements in [5] and [6] concerning the validity of testimonial claims made by forensic expert

witnesses found their way into defense briefs seeking to exclude such evidence. The Chair of [5] wrote an affidavit stating that the committee did not intend to offer any “commentary on the admissibility of firearm-related toolmark evidence.” Standard language disclaiming an explicit position on admissibility in [6] found its way into prosecution briefs arguing that the report had no bearing whatsoever on the admissibility question. The Co-Chair of [6] responded in a speech, calling this “a blatant misstatement of the truth” (Edwards, 2010). Although most NRC reports should not be read as taking a position on the admissibility question, that is no reason for them not to be treated as useful – indeed, weighty – resources for a judge making an admissibility decision.

Curiously, however, [1] has had almost no impact on admissibility rulings. Only 4 of 12 federal admissibility decisions on voice spectrography issued after the publication of [1] even cite the report at all, and, according to legal scholars, only one of those appears to have “actually read and learned what the Report had to say.” These scholars commented: “for the most part, the courts decided the post-NAS cases as if the NAS Report did not exist” (Faigman et al., 2008: p. 522).

The exception to the general rule that NRC reports avoid opining on legal issues was [4]. One scholar has estimated that one-quarter of [4]’s recommendations concerned legal issues, primarily about what form testimony should take. In addition, [4] undertook a detailed analysis of the admissibility of comparative analysis of bullet lead (CABL). Finding that CABL had difficulty satisfying any of the indicia of admissibility enumerated by the United States Supreme Court, the Report nonetheless concluded that CABL was not necessarily inadmissible, an analysis that has been criticized by legal scholars.

Admissibility aside, some forensic reports have offered other legal conclusions. For instance, [2] recommended that judges take judicial notice of the foundations of forensic DNA profiling.

Dissemination

Although some earlier reports were published by commercial publishers, the reports published after 1990 were all published by the National Academies Press (NAP). As of 2011, all those reports are available for free .pdf download from the press’s website. The NA often issues press releases to coincide with the publication of reports and otherwise endeavors to manage the dissemination of reports’ findings in the media. Some committee members lecture widely about the reports they co-authored. Nonetheless, disputes with the press sometimes arise. In the case of [2], the NRC persuaded the leading US newspaper, the *New York Times*, to publish a correction to its initial story about the report and added a clarifying statement to the final published report claiming the initial *Times* coverage had “seriously misrepresented the findings of the committee.” Most of [7], other than a rather general summary, was classified.

Impact

Because of the prestige and authority of the NA, NRC reports tend to be highly influential in scientific literature, public

policy debates, and law. US case law has recognized the expertise of the NA on scientific and technical matters and recognized NRC reports as authoritative on a wide range of scientific and technical topics.

The impact of the forensic reports has varied. Reports [2] and [3] have been highly influential. They have been cited in numerous federal and state cases, and they have provoked vigorous debate in the academic literature. Reports [3] and [6] have been cited by the United States Supreme Court. Report [6] shows signs of becoming a highly cited report, and has also provoked a great deal of discussion in the academic literature. Reports [1], [4], and [5] have been much more modestly cited in legal cases. Reports [7] and [8] have never been cited in legal opinions.

Many of the reports’ recommendations may be seen as having been highly influential and having effected changes, such as [3]’s recommendations for how to report forensic DNA associations. Reports [1] and [4] are generally understood to have played a large role in the discontinuation of forensic techniques by the requesting agency, the FBI. In the latter case, this led to the effective end of the use of CABL in the United States. The report [5] may be understood as having effectively killed off for the time being the notion of building a national ballistics database. Other recommendations have never been enacted, such as [2]’s recommendation that DNA databases be made available for scientific research. Committees’ recommendations to create new agencies have had mixed success. While some might argue that [2]’s recommendation for the creation of a National Committee on Forensic DNA Typing was met by the creation of the DNA Advisory Board, others might argue that the latter body violated [2]’s call for an agency independent of law enforcement and the laboratory promoting the technology. The fate of the National Institute of Forensic Science, called for by [6], remains similarly uncertain.

Given their role as ‘consensus studies,’ some NRC reports manage to crystallize a consensus from a range of scientific – and public – opinion, while others generate some degree of criticism from the parties who generated the scientific controversy in the first place. The forensic reports have been no exception. The reports have generated both applause and intense criticism. The report [2], in particular, generated a great deal of debate in the scholarly literature and the convening of a second committee on the same topic, which produced [3]. Report [6], likewise, has generated a great deal of public and scholarly discussion, and it has been both applauded and criticized. When parties are dissatisfied with NRC reports, they employ a number of strategies which include attacking the composition of the committee, attacking the report’s representation of scientific knowledge, charging COI, and highlighting uncertainty. These same strategies were also visible for the forensic reports. Outside parties attacked the composition of committees, complaining, for example, that [2] lacked expertise in population genetics, that [3] contained too much population genetics and statistics at the expense of other relevant expertise, that [4] lacked expertise in metallurgy, and [6] in pattern recognition evidence. Outside parties have also criticized reports’ characterizations of the state of scientific knowledge and, in some cases, highlighted the state of uncertainty of that knowledge.

American Academy of Forensic Sciences (AAFS)

MM Houck, Consolidated Forensic Laboratory, Washington, DC, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

The American Academy of Forensic Sciences (AAFS) is a multi-disciplinary professional organization that provides leadership to advance science and its application to the legal system. The objectives of the Academy are to promote professionalism, integrity, competency, education, foster research, improve practice, and encourage collaboration in the forensic sciences.

AAFS is a nonprofit, professional organization founded in 1948 in an effort to improve the effectiveness of justice through the application of scientific expertise to the legal process, evidence gathering, and crime investigation. AAFS is also dedicated to educating the law enforcement, legal, and scientific communities about the many scientific disciplines that have given rise to modern forensic science, and the application of scientific forensic techniques. AAFS is dedicated to the promotion of training programs for professionals, the exchange of information among the scientists of the above disciplines, the development of new forensic techniques, the advancement of forensic sciences, the support of new research, and the development of emerging forensic techniques and disciplines. Another AAFS goal is to preserve and impart ethical standards of professional conduct among its members. The AAFS is also the resident organization for the Forensic Science Educational Program Accreditation Commission (FEPAC), which accredits forensic science educational programs.

AAFS publishes the *Journal of Forensic Sciences*, and holds an annual scientific meeting along with several regional seminars. The Academy also provides educational information to the general public and to those considering pursuing a career in one of the many fields of the forensic sciences. Programs of continuing education and accreditation in forensics for professionals and college graduates are another service the AAFS provides. Its 6260 members are divided into 11 sections spanning the forensic enterprise:

- criminalistics
- digital evidence

- engineering sciences
- general
- jurisprudence
- odontology
- pathology and biology
- physical anthropology
- psychiatry and behavioral science
- questioned documents
- toxicology

Representing all 50 United States, Canada, and 62 other countries worldwide, they actively practice forensic science and, in many cases, teach and conduct research in the field as well. Each section provides opportunities for professional development, personal contacts, awards, and recognition. Many sections publish periodic newsletters and mailings which keep their members abreast of activities and developments in their field.

Australian and New Zealand Forensic Science Society (ANZFSS)

MM Houck, Consolidated Forensic Laboratory, Washington, DC, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

The Australian Forensic Science Society was formed in 1971 with the aim of bringing together scientists, police, criminalists, pathologists, and members of the legal profession actively involved with the forensic sciences. The Society's objectives are to enhance the quality of forensic science providing both formal and informal lectures, discussions and demonstrations encompassing the various disciplines within the science. It was decided in 1988 that the Australian Forensic Society should recognize its New Zealand members and changed its name to the Australian and New Zealand Forensic Science Society (ANZFSS).

The society holds an international symposium every 2 years. The meeting and symposia cover the major areas of forensic science – toxicology, biology, odontology, pathology, crime scene, firearms, arson, explosions, fingerprints, homicide, disasters, documents, and drug-associated crime – disciplines related to both medicine and the law.

Currently, the Society has members from all states and territories in Australia and New Zealand. There is a branch of the Society in each state of Australia, in the Australian Capital Territory, and in New Zealand. Each of these appoints a delegate to the National Council. The ANZFSS accepts membership from all persons with bona fide interests in forensic science

and it has drawn up a Code of Ethics for its members. Individual branches have regular newsletters which promote meetings and lectures of interest. Another role of the Society is to organize and fund visits by forensic specialists from interstate and overseas. Local branches hold regular meetings and visits to places of forensic interest. These meetings usually involve lectures by experts in their field and provide opportunities for members and guests to meet in an informal atmosphere. Most meetings are open to guests to attend.

American Society of Crime Laboratory Directors (ASCLD)

MM Houck, Consolidated Forensic Laboratory, Washington, DC, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

The American Society of Crime Laboratory Directors (ASCLD) is a nonprofit professional society of forensic laboratory directors and forensic science managers dedicated to providing excellence in forensic science through leadership and innovation. The purpose of the organization is to foster professional interests, assist the development of laboratory management principles and techniques; acquire, preserve, and disseminate forensic-based information; maintain and improve communications among forensic laboratory directors; and to promote, encourage and maintain the highest standards of practice in the field. The organization has a yearly symposium devoted to providing training in leadership and management techniques. The ASCLD website (www.asclcd.org) is maintained and monitored with updates that contain current news and business items for our members.

The ASCLD organization originated with a meeting in the fall of 1973, where a group of 30 forensic laboratory directors met at the FBI Academy in Quantico, Virginia. Although called there by FBI Director Clarence Kelly, it was Briggs White, Director of the FBI Laboratory, who chaired and directed the meeting. At that meeting, a steering committee under the chairmanship of Richard Fox, was formed and later met in Kansas City, MO, USA in the spring of 1974. A constitution was drafted, and in the fall of 1974 ASCLD held its first meeting at the FBI Academy.

ASCLD is composed of forensic laboratory directors, managers, and supervisors from the United States, Canada, Puerto Rico, Virgin Islands, China, Costa Rica, Finland, Hong Kong, Ireland, Italy, England, Israel, Sweden, Switzerland, New Zealand, Singapore, Taiwan, Turkey, and Australia. The membership consists of biologists, chemists, document examiners, physicists, toxicologists, educators, instructors, and law enforcement officers whose major function is the management of a forensic laboratory.

There are three kinds of membership (regular, retired, and academic affiliate) in ASCLD. Regular membership is open to all individuals whose major duties include the management or direction of a forensic laboratory, a branch forensic laboratory, or a forensic laboratory system. Retired membership is open to all individuals who have been regular members in good standing for at least 5 years, and who are no longer eligible for regular membership for reasons such as retirement, change in responsibilities, or promotion. Academic affiliate membership is open to all individuals who are educators and/or instructors of forensic science currently employed by an institution of higher learning or public law enforcement training academy. As a volunteer not-for-profit organization, all of ASCLD's board of directors, officers, committee members, and representatives

are volunteers who have a full-time management position in a forensic laboratory.

Accreditation

ASCLD is not an accrediting body. During the same time period that ASCLD was being born, a national voluntary proficiency testing program was initiated and carried out. The results reported there were serious concerns about the quality of work performed in some of the nation's forensic laboratories. The newly formed ASCLD recognized that action must be taken to establish standards of operation for crime laboratories and to take appropriate steps to restore public confidence in the work performed by the nation's crime laboratories. As a result, a committee was appointed by ASCLD to consider and worked on various programs that could be used to evaluate and improve the quality of laboratory operations. The committee considered individual certification, a self-assessment program and an accreditation program based on external peer review as a possible means of achieving the goal. The committee eventually became the ASCLD Committee on Laboratory Accreditation and a program of laboratory accreditation was approved in concept by the ASCLD membership in the fall of 1980 and on 11 June 1981, the committee held an organizational meeting in Quantico. To the confusion of many, its name continues to reflect its origins and is now known as The American Society of Crime Laboratory Directors/Laboratory Accreditation Board, or ASCLD/LAB (www.asclcd-lab.org).

European Network of Forensic Science Institutes (ENFSI)

MM Houck, Consolidated Forensic Laboratory, Washington, DC, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

The European Network of Forensic Science Institutes (ENFSI) has been established with the purpose of sharing knowledge, exchanging experiences and coming to mutual agreements in the field of forensic science. ENFSI is recognized as an expert group in the field of forensic sciences. It works to

- strengthen and consolidate ENFSI;
- expand the membership throughout Europe while maintaining the development and credibility of ENFSI;
- establish and maintain a working relationships with other similar organizations; and
- encourage all ENFSI laboratories to comply with best practice and international standards for quality and competence assurance.

ENFSI activities include

- organizing meetings and scientific seminars, collaborative studies and proficiency tests;
- advising relevant partners on forensic issues; and
- publishing best practice manuals and glossaries of forensic terms in several languages.

In 1992, the directors of Western European governmental forensic laboratories agreed that they should hold regular meetings to discuss topics of mutual interest. At the first meeting in 1993 in Rijswijk (The Netherlands) 11 laboratories were represented. It was agreed that membership of ENFSI would be open to countries from the whole of Europe. The formal Founding Meeting took place on 20 October 1995 in The Hague and is considered to be the official birthday of ENFSI. Here, the founders of ENFSI signed the Memorandum of Understanding governing the operation of the Network, the first regular Board was elected and the logo was introduced. At the Annual Meeting 1999 in Moscow, the first Constitution for ENFSI was accepted by the membership. In that same year, the ENFSI website was established. In 2002, a Secretariat was established for a trial period, financed from the – new introduced – members fees. The Netherlands Forensic Institute volunteered for hosting the Secretariat. A new ENFSI Constitution was approved in 2004. The main features were the transformation from a Personal membership into an Institutional membership as well as the definite introduction of an Annual fee. In 2009, the European Community recognized ENFSI as a so-called monopolist, that is, it is considered as the sole voice of the forensic community in Europe.

ENFSI has 16 Expert Working Groups which serve as the advisory, consensus-standard setting, and scientific arms of ENFSI:

- Digital imaging
- DNA
- Document
- Drugs

- Explosives
- Fingerprint
- Fire and explosions investigation
- Firearms
- Forensic information technology
- Forensic speech and audio analysis
- Handwriting
- Marks
- Paint and glass
- Road accident analysis
- Scene of crime
- Textile and hair

ENFSI has three Standing Committees for key areas and a fourth operational committee. The Quality and Competence Committee (QCC) develops policies on Quality Assurance and Competence Assurance, provides advice to the Expert Working Groups and ENFSI members, and helps the ENFSI laboratories to comply with best practice and international standards. The Education and Training Committee (E&T) coordinates E&T activities and stimulating E&T initiatives, provides advice to the Expert Working Groups and ENFSI members, and facilitates the communication between agreed external training institutions, the ENFSI organization and ENFSI member. Finally, the Research and Development Committee (R&D) develops and maintains ENFSI's Research and Development Strategy, provides advice and information to Expert Working Groups and ENFSI members on relevant research and development topics, and facilitates joint-research between laboratories internationally.

The role of the fourth Committee, the European Academy of Forensic Science (EAFS) is limited to the organization of triennial meetings. EAFS acts as the strategic advisor to ENFSI on matters of Research and Development in a broad sense. The aims of the EAFS are to provide leadership and focus on matters of Research and Development to ENFSI, improve knowledge transfer between individual stakeholder groups (scientists, police, and lawyers), researchers and practitioners, and improve the funding of ENFSI research topics.

International Association for Identification (IAI)

MM Houck, Consolidated Forensic Laboratory, Washington, DC, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

In August 1915, a number of 'Criminal Identification Operators' met in Oakland for the purpose of forming an organization to further the aims of the identification profession. A group of 22 men met and, as a result, the 'International Association for Criminal Identification' was founded in October 1915. In 1918, at the fourth annual conference, the word 'Criminal' was dropped from the name of the Association, in recognition of the volume of noncriminal work done by identification bureaus. On 22 December 1919, the International Association for Identification (IAI) was incorporated under the laws of the State of Delaware. The IAI is committed to six objectives. In brief, to associate persons in the forensic science profession, keep them up to date and informed, advance the relevant sciences, encourage research, provide training, education, and to the dissemination of this information through its publications thereby fostering a relationship among forensic practitioners worldwide.

In 1958 the Association established the John A. Dondero Memorial Award in honor of his many contributions to the field of identification. It is the highest honor an IAI member can receive. It is awarded for the most significant contribution in the area of identification and allied sciences during the calendar year immediately preceding each annual conference. Its first recipient was J. Edgar Hoover.

By 1990, the Crime Scene Certification Program was functioning with a comprehensive testing process for three levels of certification. The IAI now has seven Certification Programs including:

- Forensic Art,
- Footwear and Tiretrack Analysis,
- Bloodstain Pattern Analysis,
- Forensic Photography/Imaging,
- Tenprint Fingerprint Certification, and
- Latent Print.

The IAI has published the *Journal of Forensic Identification*, a peer-reviewed journal with original technical articles and case reports, since 1988.

The IAI's Annual Educational Conferences features many workshops and presentations given by leading experts in forensic identification and related fields. The IAI is an international association with conferences held in the United States as well as elsewhere.

To qualify for 'Active Membership' status, an individual must be employed by a local, county, state or federal unit of government subdivision thereof and actively involved in forensic science. 'Distinguished Membership' is open to current IAI members who meet certain criteria. Individuals not qualified for 'Active Membership' may qualify for 'Associate Membership.' That category includes those employed in some

aspect of forensic science outside of government, vendors to the forensic sciences and students, to name a few. 'Student Membership' is a category of membership available to full-time college students at an accredited college with a major in a law enforcement and/or a forensic science-related field.

The IAI Collection

In 2005, the IAI selected the West Virginia University (WVU) Libraries to house its priceless research library due in part to WVU's pioneering program in the field of Forensic and Investigative Sciences education. Consisting of more than 100 linear feet of material, including archives and manuscripts, books, periodicals, and a wide assortment of ephemeral publications, the IAI collection is the most comprehensive forensics information resource in existence. Included are materials dating back to late nineteenth century when the field of scientific criminal investigation was in its infancy. Among the earliest and most valuable items in the IAI collection are the scrapbooks of Dr. Henry Faulds (1843–1930). A towering figure in the history of forensic sciences, it was Faulds who first recognized the value of fingerprints to criminal identification. The Faulds scrapbooks include research notes, original drawings and studies of fingerprint patterns and typology, as well as correspondence with individuals and crime fighting organizations around the world, dating from the late 1870s until shortly before the doctor's death in 1930.

National Association of Medical Examiners (NAME)

MM Houck, Consolidated Forensic Laboratory, Washington, DC, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

The National Association of Medical Examiners (NAME) is the national professional organization of physician medical examiners, medical death investigators, and death investigation system administrators who perform the official duties of the medicolegal investigation of deaths of public interest in the United States. NAME was founded in 1966 with the dual purposes of fostering the professional growth of physician death investigators and disseminating the professional and technical information vital to the continuing improvement of the medical investigation of violent, suspicious, and unusual deaths. NAME has expanded its scope to include physician medical examiners and coroners, medical death investigators, and medicolegal system administrators from throughout the United States and other countries.

NAME members provide the expertise to medicolegal death investigation that is essential to the effective functioning of the civil and criminal justice systems. NAME is now the national forum for the interchange of professional and technical information in this important segment of public administration. NAME seeks to promote excellence in the day-to-day investigation of individual cases as well as to improve the interaction of death investigation systems with other agencies and political entities that interface with death investigation in each jurisdiction in this country.

The evolution of excellence in the medicolegal investigation of death in the United States has been slow and arduous. In many jurisdictions the medical aspects of death investigation remain relegated to personnel without medical training, or are performed by persons with little or no education in death investigation. NAME serves as a resource to individuals and jurisdictions seeking to improve medicolegal death investigation by continually working to develop and upgrade national standards for death investigation. The published NAME Standards for a Modern Medicolegal Investigative System provide a model for jurisdictions seeking to improve death investigation. NAME aims to involve competent professional medicolegal death investigators in every jurisdiction in the United States.

NAME, as an association and through its members, maintains active cooperative relationships with the College of American Pathologists, American Society of Clinical Pathologists, and other professional organizations. NAME representatives participate and serve in an advisory capacity to federal, public, and private organizations on projects of mutual interest. As the official specialty association of physician medical examiners, the NAME promotes its vision of competent national death investigation from a seat in the House of Delegates of the American Medical Association. The educational functions of NAME are simultaneously directed toward the development and improvement of administratively efficient, cost

effective death investigation systems. The Association serves as the national forum for medical death investigators and system administrators for the discussion and dissemination of such information. NAME further encourages members to participate in the training of law enforcement officers, allied health professionals, paramedical personnel, and others who interface with death cases.

The work of the Association is carried out under the direction of its Officers and a Board of Directors elected by the membership. An executive committee is responsible for the fiscal affairs and management of the Association. Standing committees deal with issues of membership and credentials, education, program and publications, ethics, standards, inspection, and accreditation, and finance amongst others. All members are encouraged to participate in the committee activities. A permanent Executive Director and part time Executive Vice-President, headquartered in Atlanta, provide year-long administrative support.

As part of its mission to improve the quality of death investigation nationally and to recognize excellence in death investigation systems, the NAME offers a voluntary inspection and accreditation program for medicolegal death investigative offices. This program is designed to offer expert evaluation and offer recommendations for the improvement of functioning offices. Accreditation by NAME is an honor and significant achievement for an office. It signifies to the public that the office is performing at a high level of competence and public service. NAME also offers consultative services for jurisdictions seeking to establish medicolegal death investigation systems and for political entities wishing to evaluate death investigation systems under their administrative purview.

Membership in the NAME is open to all physicians, investigators, and administrators who are active in medicolegal death investigation.

Membership is comprised of Fellows, Members, Affiliate Members, and Emeritus Members. Fellows are physician medicolegal death investigators who are either (1) certified in forensic pathology by the American Board of Pathology or its international equivalent as determined by the Board of Directors or (2) prior to 2008 have completed a training program in forensic pathology that is accredited by the Accreditation Council on Graduate Medical Education or have been officially 'qualified for examination' in forensic pathology by the American Board of Pathology. Members are physician medicolegal death investigators other than those meeting the criteria designated in the definition of Fellow. The Member category includes pathologists, forensic pathology fellows, physician medical examiners, and physician coroners at the time of their application. Resident members are pathology residents who are involved in pursuing a career in any field that allows Association membership as delineated

above. Affiliate members are those who assist Fellows or Members at the time of their application for membership, members of military commands who conduct death investigations, administrators within an official death investigation system, persons having expertise utilized by or affiliated with Fellows or Members in the official investigation of deaths, nonconsultant support personnel who assist Fellows, Members, other Affiliates or others in performing death investigation or other forensic duties, and Trainee Affiliates who are students beyond high school graduation who are involved in pursuing a career in any field that allows Association membership. Emeritus Members are those members in any of the categories described above who have had specified years of NAME membership and are fully retired from the practice of forensic science.

Senior Managers of Australian and New Zealand Forensic Laboratories (SMANZFL)

MM Houck, Consolidated Forensic Laboratory, Washington, DC, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

The Senior Managers of Australian and New Zealand Forensic Laboratories (SMANZFL) are the group of the Directors of all forensic science organizations, scientific and police in Australia and New Zealand. SMANZFL meets formally once a year, but out-of-session meetings are held throughout the year. The role of SMANZFL is to promote leadership in the forensic sciences in the pursuit of excellence. Its functions are to

- provide leadership and best management practice in the forensic sciences,
- promote interaction and cooperation with stakeholders,
- promote science excellence,
- contribute to policy issues in the justice system,
- promote confidence in the forensic sciences, and
- promote efficient and effective use of resources

SMANZFL is supported by eight Specialist Advisory Groups (SAGs) which advise SMANZFL and influence discussions on technical systems, science infrastructure, research and development, training, quality, legislative policy, and communications. SMANZFL is the conduit for the SAGs which report to and through SMANZFL. There are eight SAGs that represent forensic scientists in the disciplines of:

- Medical sciences
- Biology
- Chemical criminalistics

- Document examination
- Field and identification sciences
- Toxicology
- Illicit drugs
- Electronic evidence

The SMANZFL Executive has responsibility for the promotion of and advice to the SAGs. The SAGs comprise specialists from each of the organizations represented by SMANZFL. They meet formally once a year but out-of-session meetings are held throughout the year.

Glossary

Cytochrome P450 (CYP 450) A superfamily of enzymes, some polymorphically expressed, catalyzing oxidation of organic substances including xenobiotics involved in drug metabolism and bioactivation.

G-Protein-coupled receptor kinases (GRKs) Enzymes that regulate guanine-protein-coupled receptor activity by phosphorylating their intracellular parts after release and activation of associated G-proteins as mediators of tolerance via up- and downregulation.

Pharmacogenomics/toxicogenomics Deals with the influence of genetic variation on xenobiotic response in humans by correlating gene expression or single-nucleotide polymorphisms with a drug's efficacy or xenobiotic toxicity.

Xenobiotics Substances found in humans that are not normally produced or expected to be present, or substances present in much higher concentrations than are usual.

Abbreviations

CNS Central nervous system
DFSA Drug-facilitated sexual assault
GABA γ -Aminobutyric acid, the main inhibitory neurotransmitter in human central nervous system, regulating neuronal excitability and muscle tone

GHB γ -Hydroxybutyric acid is naturally occurring in human CNS in small amounts and is considered as an illicit drug (liquid ecstasy) in many countries
UV Ultraviolet

Introduction

From Antiquity to the sixteenth century, it was difficult or even impossible to perform an autopsy and prove poisoning. Proof was made by gossip, the circumstances, for example, discoloration of the corpse, suspect poisons found, confession, or by torturing the alleged culprit. Progress in toxicological analysis had to wait until the nineteenth century – a transition period of medical mindset between natural philosophy and natural sciences. Many famous criminal poisoning cases were milestones in toxicology, contributed to its progress, and can be used as a source of information for the interpretation of toxicological results. At court trials, experts had to make great efforts, as their analytical results and interpretations were challenged by lawyers, prosecutors, magistrates, and counter-experts. Modern analytical toxicology has made expert opinions less hazardous. Even if ‘experts’ battles’ did not always increase the toxicologist’s reputation, the progress of science occurred. Experts became more aware of the limited performance of analytical toxicology, with the aim to give better evidence to judicial authorities. Before the twentieth century, homicidal poisoning was far more popular than it is today, even though there are many more poisons available now.

Poisons were difficult to detect before 1800 and the legislation was inadequate to assist investigators in proving that a crime was committed. In response to many criminal cases, forensic toxicology developed, making detection increasingly more likely, and the sale of poisons became better controlled through strong legislation. Victims remained the same over the years: unwanted husbands, wives or lovers, illegitimate babies, children, rivals, employers, and individuals killed for monetary gain, but mostly cases were concerned with family disputes.

Important Historical Milestones

Since approximately 50 000 BC, humanity was aware of the difference between some safe and unsafe plants, animals, or minerals probably as a result of their experiences including mishaps. Mythology, philosophy, folklore, shamanism, and religious rituals rather than science with observation, experiments, and theories guided beliefs and knowledge.

Antiquity Middle Ages and Renaissance

Since the Sumerians (3500–2000 BC), knowledge about poisons had improved only slowly until the eighteenth century.

In 1302, Bartolomeo da Varignana (1255–1321) performed the first autopsy in Bologna to investigate a poisoning case, according to a decision in 1209 by Pope Innocent III (1160–1216) and that by Gregory IX (1145/1170–1241) in 1234 to anchor medicolegal expert opinion in the *Corpus Iuris Canonici*, in case of death of a suspect.

In 1538, Paracelsus (1493–1541) formulated a fundamental statement *Dosis sola facit venenum*, a cited version in Latin from the eighteenth century, but originally written in old German: *Alle Ding’ sind Gift, nichts ohn’ Gift, allein die Dosis macht dass ein Ding kein Gift ist*.

Evolution from the Eighteenth to the Twenty-First Century

In 1758, a Paracelsus similar statement *Alimenta a toxicis, uti medicamenta a venenis, non natura sed dosis distinguit* was formulated by Carolus Linnaeus (1707–78).

In the Mary Blandy (1720–52) criminal case, in which the accused was charged of poisoning her father Francis from Henley-on-Thames in a trial at Oxford in 1752, the first known chemical test ever for arsenic detection was performed by medical examiner Anthony Addington (1713–90) from Reading. This test looking primitive by today’s standards was innovative in the eighteenth century. Addington heated a white powder found on a victim’s pan and noticed the same garlic odor and whitish smoke as that of similarly treated arsenic.

A more reliable arsenic detection and quantification method was published in 1836 by James Marsh (1789–1846).

A systematic approach to toxicity and detection of poisons was outlined by Mateo José Bonaventura Orfila (1787–1853) in his most famous textbook *Traité des poisons tirés du règne minéral, végétal et animal ou toxicologie générale* published in 1814. He was the first who considered detecting mineral poisons in the so-called ‘second route’ of administration and elimination. Few years later, in 1839, Orfila used Marsh’s method for the detection of As in the famous Lafarge trial in France. Orfila’s work was continued in the United Kingdom, notably by his students Robert Christison (1797–1882) at Edinburgh University and Alfred Swaine Taylor (1806–80) at Guy’s Hospital, London, and in Sweden by Jöns Jacob Berzelius (1779–1848) at Karolinska Institute, Stockholm. Other toxicologists, notably Thomas Stevenson (1838–1908), followed Orfila’s work at Guy’s Hospital and became involved in many famous trials for criminal poisoning.

In 1838, a separation scheme for inorganic cations using H_2S was proposed by Carl Remigius Fresenius (1818–97), and in 1841, Hugo Emil Reinsch (1809–84) used a copper wire in acidic solutions to detect Hg, As, Bi, and Sb in biological samples by forming a gray deposit (as As_2Cu_5). A screening method for mineral poisons in a biological material was proposed in 1845 by Carl Remigius Fresenius (1818–97) and in 1847 by Lambert Heinrich von Babo (1818–99).

Jean-Servais Stas (1813–91) was the first to perform the isolation of alkaloids, notably nicotine, from biological specimens by solvent extraction using diethyl ether after deproteination with ethanol.

In 1859, Robert Bunsen (1811–99) and Gustaf Kirchhoff (1824–87) discovered flame emission spectrometry for mineral elements. Detection of white phosphorus was published in 1855 by Eilhard Mitscherlich (1794–1863).

In 1856, Friedrich Julius Otto (1809–70) proposed a modification of Stas’ method to a systematic method for the extraction of nonvolatile acidic and basic compounds.

From 1830 onwards, subsequent tests for alkaloid identification were developed, either precipitation tests or color tests with more or less specific and sensitive reagents, some of which are still used today. Before these chemical tests became available, toxicologist had to use the typical odors or bitter taste of many poisons to identify them.

The first ever reported precipitation test for alkaloids by Ferdinand Ludwig Winckler (1801–68) in 1830 used HgCl_2 and KI solutions, modified later and became the Mayer reagent (1863), the De Vrij test (1854), the Merck test (1855), the

Julius Nessler test, and so on. Analogous reagents came up as the Wagner reagent (1866), the Marme reagent (1866), and the Dragendorff reagent (1866). Other color tests were developed, notably the Erdmann test (1861), the Fröhde test (1866), the Pellagri test, the Vitali test (1880), the Mandelin test (1884), the Marquis test (1896), and the Mecke test (1899), for general detection of alkaloids and nitrogenous bases or for some specific chemical drug families.

Francesco Selmi (1817–81) was the first to doubt the reliability of color reactions for forensic toxicological purposes, because of interference with physiological components of various organs, such as ptomaines generated by postmortem degradation. Other tests were developed later, notably the Paul Ehrlich reagent, also known as the van Urk reagent, to detect lysergic acid diethylamide (LSD) and other indolalkylamine hallucinogens and the Bratton–Marshall test (1939) for the quantification of sulfonamides. Later, this method was adapted for amino group-containing parathion metabolites (known as Averell–Norris reaction) and for benzodiazepine derivatives by Harald Schütz; the Schiff (1834–1915) test was adapted for the detection of aldehydes; the Fujiwara test was adapted to detect chloroform; and the Dille–Koppanyi reagent was modified by Zwikker for barbiturate detection (1934). In the 1950s, the Forrest test and the ferric chloride/perchloric acid/nitric acid reagent test were introduced for the presumptive testing of imipraminic antidepressants or +phenothiazines. In the 1960s, the Duquenois–Levine reagent as well as Fast Blue salt B was used for presumptive testing of cannabinoids and the Scott test was used for cocaine testing in 1973.

In 1931, Fritz Feigl proposed an important textbook on spot tests. Several tests using precipitation reagents with subsequent microscopic examination of the obtained crystals, or if solid compounds could be isolated by extraction, recrystallization, and subsequent melting point determination according to Kofler (1891–1951), can be performed. Pure liquids could be identified by their refractive indices.

When no chemical test was available, physiological tests were applied, notably the tetanic spasms in frogs (1856) for strychnine detection, the mydriasis test of cat eyes described by Friedlieb Ferdinand Runge (1795–1867) for atropine detection, the taste test giving peculiar numbness of the tongue with aconitine, the Straub–Hermann mouse tail test for morphine given by subcutaneous administration producing a characteristic S-shaped dorsiflexion of a mouse tail, and the asystole test observed in 1856 on isolated frog heart by Rudolf Böhm (1844–1926) and Claude Bernard (1813–78) for digitalis detection.

Biological assays using the vinegar fly *Drosophila melanogaster* to screen for some insecticides in body tissues were proposed in the 1960s.

In 1924, Louis Lewin (1850–1929), considered as the father of psychopharmacology, published a pharmacological classification of psychotropic drugs and several papers on hallucinogenic plants.

Salting out of organ material with ammonium sulfate was proposed by L.C. Nickolls in 1937 and with sodium tungstate was proposed by Paul Valov in 1946.

Microdiffusion methods to detect cyanides, carbon monoxide, and so on, were proposed in 1947 by Edward J. Conway (1894–1965).

From 1920 onward, important discoveries in molecular pharmacology, such as neurotransmitters, second messengers,

and signaling proteins, were made, allowing progress in understanding action mechanisms of psychotropic substances. In line with this, acetylcholine was discovered by Otto Loewi (1873–1961). Noradrenaline (norepinephrine) was discovered by Ulf von Euler (1905–83) in 1946 and its metabolism extensively studied by Julius Axelrod (1912–2004). In 1948, Maurice M. Rapport, Arda Green (1899–1958), and Irvine H. Page (1901–91) discovered a vasoconstrictor substance serotonin, aka 5-hydroxytryptamine or 5HT, in blood serum with a broad range of physiological roles. Discovery of dopamine in 1957 by Arvid Carlsson (1923–2008) led to the development of new antidepressant drugs. In 1950, Eugene Roberts (1920–) and Jorge Awapara (1918–2005) independently reported the discovery of γ -aminobutyric acid (GABA) in mammalian central nervous system. After several years of research, Ernst Florey (1927–97) proposed in 1957 that GABA would be an inhibitory neurotransmitter.

Cyclic adenosine monophosphate was isolated in 1956 by Earl W. Sutherland Jr. (1915–74). Alfred G. Gilman pioneered in the domain of G-protein-coupled receptor kinases. Moreover, an important step was the discovery of opioid receptors by Eric Simon et al., followed by the discovery of opioid neuropeptides in 1974 by two independent investigators: John Hughes, Hans Kosterlitz et al. isolated enkephalins from a pig brain and Rabi Simantov and Solomon H. Snyder isolated endorphins from calf brain.

In 1957, Jean Delay (1907–87) and Pierre Deniker (1917–98) published a new useful pharmacological classification of psychotropic drugs.

Evolution of Drugs and Poisons

Since Antiquity, humans have known that plants of the nightshades family have mind-altering properties and used them as hexing herbs associated with witchcraft, notably *Atropa belladonna*, *Mandragora officinarum*, *Datura stramonium*, *Brugmansia* spp, and *Hyoscyamus niger*.

Ethanol is one of the oldest known and remains by far the most frequently used recreational substances. The first benzodiazepine discovered by Leo Sternbach (1908–2005) in 1957 was launched as LIBRIUM and introduced as ‘a tranquilizer that relieves tension without causing apathy,’ followed in 1963 by diazepam VALIUM, and many other tranquilizers later.

Amphetamines and Designer Drugs

In 1887, Lazar Edeleanu (1861–1941) synthesized amphetamine, and methamphetamine was first synthesized from ephedrine in 1893 by Nagai Nagayoshi (1844–1929) and later in 1919 by Akira Ogata (1887–1978).

3,4-Methylenedioxymethamphetamine was first synthesized in 1912 by Anton Köllisch (1888–1916) at Merck Co (Darmstadt). In the mid-1970s, Alexander Shulgin (b1925) synthesized some 200 structural analogs with even more potent activities and studied their psychotropic effects on students. His book PIHKAL, an acronym for *Phenethyl Amines I have known and loved*, gives detailed recipes for clandestine laboratories. Later, hundreds of so-called designer drugs, which are structurally related to existing illicit drugs, appeared on the street scene especially via massive Internet sale called legal highs, mostly labeled as ecstasy, until they were also

scheduled. In 1997, by European Council decision, the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA) based in Lisbon and Europol were charged with setting up an early warning system to monitor emerging new synthetic psychoactive drugs and to provide rapid information and risk assessment on the same to its member states.

Cocaine

For over 1000 years, native Latin Americans used *Erythroxylon coca* as a stimulant and as an anesthetic during trepanation. Cocaine was first isolated by Friedrich Gaedcke in 1855. The first synthesis and molecular structure elucidation was made by Richard Willstätter in 1898. In 1863, Angelo Mariani (1838–1914) marketed a wine treated with coca leaves, which was called Vin Mariani. Cocaine was introduced for clinical use in 1884 as a local anesthetic in Germany.

LSD

In the Middle Ages, human poisoning due to rye bread consumption was rather common in Europe, generating epidemics controversially linked to ergot poisoning, notably Saint Anthony's fire, the dancing procession of prayers in Echternach/Luxembourg to honor Saint Willibrord (658–739), and the hysterical behavior of young women accused of witchcraft in colonial Massachusetts in 1692, resulting in the Salem witch trials. LSD was synthesized in 1938 by Albert Hoffmann and its psychedelic properties were discovered in 1943. Dr. Timothy Leary was the most prominent pro-LSD researcher in the United States in the 1950s and 1960s.

Opioids

In 1804, Friedrich Wilhelm Sertürner (1783–1841) isolated morphine, the alkaloid, in a pure state from *Papaver somniferum*. The invention in 1850 of the hypodermic syringe by Charles Pravaz (1791–1853) and Alexander Wood (1817–84) allowed IV administration of narcotic analgesics. Heroin was discovered in 1874 by Charles Alder Wright (1844–94), synthesized in 1897 by Felix Hofmann (1868–1946) at Bayer Leverkusen, and marketed or advertised as a 'nonaddictive morphine substitute in 1899,' but the users' rates of dependence on heroin soon became one of the highest. Many other opiates and opioids have been launched over the years.

γ -Hydroxybutyric acid

Synthesis of γ -hydroxybutyric acid (GHB) was first reported in 1874 by Alexander Mikhaylov Zaytsev (1841–1910), but the first major pharmacological research was conducted by Henri Laborit by studying neurotransmitter GABA in the early 1960s. Legitimate medical uses declined rapidly, because of its use in drug-facilitated sexual assault (DFSA) and its abuse potential.

Recent Developments in Analytical Methods

Since the 1960s, there has been tremendous progress in analytical toxicology due to the development of new extraction techniques and the mushrooming evolution of chromatographic, spectrographic, and immunoassay technologies.

Extraction techniques were improved from simple liquid solvent extraction to solid-phase extraction introduced in 1949; and solid-phase micro-extraction and supercritical fluid

extraction coupled with supercritical fluid chromatography were followed and rationally adapted to be performed by robots. Thin layer chromatography pioneered by Egon Stahl (1924–86) and Dieter Waldi, gas chromatography pioneered by James and Martin, and high-performance liquid chromatography pioneered by Csaba Horvath (1930–2004) in the end of 1960s developed to one of the most performing separation technologies. Starting from Goldbaum's spectrophotometric method for barbiturates, spectrometric methods made great progress. Another revolution in analytical toxicology was pioneered by Ryhage's et al. with the application of gas chromatography coupled with mass spectrometry to toxicology, further developed by many others. Interpretation of mass spectra was made easier by the availability of spectra libraries such as the consecutive editions of the Pfleger, Maurer, and Weber Libraries in 1985, first in book format containing some 1500 mass spectra of drugs, toxicants, and metabolites, later in 1987 as software for mass spectrometry instruments, updated in 2011 with nearly 9000 mass spectra.

The emergence of immunoassays for insulin in the 1950s and subsequent development of immunoassays for drugs-of-abuse testing was followed by an automatization to run series of many specimens. Lab-on-a-chip integrates one or several laboratory functions on a single small chip, allowing the handling of <1 pl volume, for example, a biochip array technology that allows multianalyte drug screening. The knowledge of drug and poison biotransformations to allow correct interpretation of toxicological results, taking into account pharmacogenomics and toxicogenomics, as genotyping and phenotyping studies have shown inheritable mutations in drug-metabolizing enzymes, notably some cytochromes P450, was also improved.

Alternative Matrices

Since the 1990s, alternative matrices such as hair, saliva, sweat, nails, and meconium besides the classical blood and urine have become available for forensic purposes. Hair analysis is increasingly being used to detect the presence of a large number of illicit drugs, environmental pollutants, and a minor metabolite ethyl glucuronide in alcohol to detect chronic ethanol intake.

Drug-Facilitated Crime

Owing to sensitivity improvement in analytical technologies, enormous progress has been made to convict offenders in drug-facilitated crime such as DFSA where, for example, benzodiazepines or GHB is used as a date rape drug.

Drugs and Driving

Driving under the influence of drugs, having been recognized in most countries since the beginning of the 1990s, is a serious road safety issue now. Ethanol remains by far the biggest problem, but cannabis and opioids are also commonly detected drugs. Adequate legislation is not yet in place in all countries to properly detect and convict drug-impaired drivers. In some countries, debates continue on whether to enact zero tolerance or legal tolerance limits for selected drugs.

Famous Poisoning Cases

Famous Criminal Poisoning Cases from the Fifteenth to the Seventeenth Century

The Italian School of Poisoners was most famous for poisoners such as the Borgias in the fifteenth century, and in France, a similar situation was observed with the Parisian School of Poisoners starting with Cathérine de Médicis (1519–89). She was married to King Henri II in 1533 and is alleged to have transferred the knowledge on poisons in France to Italy. Later, in the seventeenth century under Louis XIV (1638–1715), the so-called *Affaire des Poisons* occurred from 1670 to 1682.

Famous Criminal Poisoning Cases from the Nineteenth to the Twenty-First Century

To illustrate the evolution of poisoning, six famous cases are outlined below.

Dr. Edme S. Castaing case 1823

In 1823, Dr Edme S. Castaing (1796–1823), for need of funds, poisoned two of his friends and patients called Ballet Brothers with morphine in Paris. At that moment, morphine was not detectable in the viscera. Scientists involved in this case were, among others, René TH Laennec (1781–1826), François Magendie (1783–1855), Louis-Nicolas Vauquelin (1763–1829), and Mateo JB Orfila (1787–1853). The poisoner was finally sentenced to death by guillotine.

Hannah Russel case 1826

Hannah Russel from Burwash, Sussex, with the complicity of her lodger Daniel Leney was suspected to have poisoned her husband with arsenic. At autopsy, a local surgeon named Thomas Evans had found arsenic. A controversial dispute on inconclusive evidence between Gideon Mantell (1790–1852) (famous discoverer in 1825 of the first dinosaur *Iguanodon* fossil in Sussex), and Sir Robert Christison (1797–1882), and Alfred Swain Taylor (1806–80) took place. Leney was executed, but Hannah was pardoned.

Dr. George Henry Lamson case 1881

Morphine-addicted G. H. Lamson used aconite to murder his handicapped brother-in-law Percy Malcolm John. Aconite was dissimulated in Dundee raisin cake, in order to secure an inheritance. Lamson had learnt about aconite – as a medical student mate of Robert Christison – that it was undetectable, but forensic science had improved since Lamson's student days. The medical/toxicological experts in court were, among others, Thomas Stevenson (1838–1908) from Guy's Hospital, August Dupré (1835–1907) from Westminster Hospital, and Walter N. Hartley who plotted the first UV (ultraviolet) Spectrum in 1881. At that trial, the criminal defense was evoked for the first time ptomaine poisoning and falsely positive alkaloid tests according to Francesco Selmi (1817–1881). At the end of the trial in Old Bailey Court in London, Lamson was hanged in 1882.

Affaire Marie Besnard 1949

Marie Bernard was accused of poisoning 11 persons including her husband with arsenic, because of a hypothetical love affair with German war prisoner Alfred Dietz in Loudun/Vienne, France. A great number of toxicologists/pathologists, notably

Georges Bérout, from Marseille Crime Laboratory charged with the first autopsy, who improperly used the Marsh and Cribier methods for As detection; Louis Truffert (b1910); Henri Griffon (1904–90) using a neutron activation method, René Piédelièvre (1891–1975), René Truhaut (1909–94), Emile Kohn-Abrest (1880–1963); René Fabre (1889–1966); Roger Le Breton (1914–97); Léon Dérobert (1910–80); Frédéric Joliot-Curie (1900–58), and Jean Keilling, Georges Schuster, Henri Ollivier, Marcel Le Peintre as counter-experts, discussed about this case for over 12 years. In a first judgment in 1952 at Poitiers Criminal Court, she was sentenced to prison, but finally in 1961 she was found not guilty at Bordeaux Appeal Court.

Christa A. Lehmann case 1954

In Worms, Germany, Lehman poisoned her husband, father-in-law, her girlfriend, and a dog, Flocky, instead of targeted girlfriend's mother with parathion in chocolate candies. At the trial, Kurt Wagner (1905–65), Hans-Joachim Wagner (b1924-), Alfred 'Meister' Brahm-Vogelsanger, Hans Kaiser, Theo Haag, Georg Schmidt (1923–2010), and Wolfgang Schwerd (b1924) were in charge of the case: At the end of the trial, she was sentenced to life in prison. After this case, a critical discussion on the forensic significance of Averell–Norris reaction in the identification of metabolite *p*-nitrophenol from parathion was triggered. As a result of this case, a decrease in parathion suicides among individuals in the state of postwar Germany was observed.

Kenneth Barlow case 1957

Barlow, a male nurse from Bradford, UK, was accused of poisoning his wife Elizabeth with insulin in an abortion tentative. A. S. Curry (1925–2007) and his crew – 'The Harrogate People' – testified. Barlow was sentenced to lifetime in prison and released, after serving 26 years, still maintaining his innocence.

Glossary

Affinity Attraction between molecules based on chemical interactions between atoms, resulting in binding of a ligand to its receptor.

Agonist A drug eliciting a response subsequent to its binding to a receptor.

Antagonism The property of blocking the effect of an agonist.

Antagonist A drug blocking responses from an agonist subsequent to its binding to a receptor.

Craving The compelling need to seek a drug for a desired effect to return.

Dependence A behavior accompanied by craving and possible physical symptoms when a drug use is terminated.

Efficacy The ability to produce a response after binding to a receptor.

G-protein A trimeric protein using GTP as a source of energy to transmit signals from outside the cell into that cell bridging receptors to an intracellular enzyme.

Induction The process of enhancing gene expression through DNA interaction with transcription factors.

Kinase Enzyme acting through phosphorylation to activate or inactivate substrates.

Phosphatase Enzyme acting through dephosphorylation to activate or inactivate substrates.

Potency A comparative measure of doses required to elicit a response. The smaller the dose, the more potent the drug.

Potentiation The property of enhancing the effect of an agonist.

Receptor The molecular target of a drug.

Repression The process of silencing gene expression through DNA interaction with transcription factors.

Sensitization An increased sensitivity of receptors, resulting in greater than expected responses for a given dose of agonist. Desensitization is the opposite.

Tolerance The loss of response to a drug in spite of its presence.

Upregulation An increased availability of receptors, resulting in greater than expected responses for a given dose of agonist. Downregulation is the opposite.

Withdrawal A syndrome of physical and psychiatric symptoms triggered by sudden cessation of drug use.

Introduction

The pharmacology of drugs results from the interaction of a chemical with endogenous receptors, and pharmacodynamics is the science concerned with the mechanisms of drug action. Although proteins are best characterized as targets for drugs to bind to, nucleic acids and complex lipids can also behave as binding sites. Pharmacologic and toxic effects can be understood through the interaction between a drug or poison and these endogenous macromolecules called receptors. More importantly in toxicology, it is the number of actual receptors that the xenobiotic binds to that best correlates with the magnitude of the effects observed. It is the complex interaction of the drug and the receptor that results in mediation of the actions of agonists and antagonists.

Affinity, Efficacy, and Potency

Drugs can be classified as agonists or antagonists of receptors. The recognition of a specific binding site is called the affinity of the drug for its target. This affinity is responsible for the selectivity of drug action. Parameters such as size, shape, charge, and solubility determine the affinity with which a particular drug will recognize a particular site to bind to. Both agonists and antagonists have affinity. When a binding elicits a response, it is called efficacy. Only agonists have efficacy (i.e., constrict blood vessels known as vasoconstriction), antagonists have zero efficacy (i.e., prevent vasoconstriction), and inverse agonists have the opposite effect (i.e., vasodilate).

Once receptors are occupied, they transmit a signal that results in a multistep biochemical and biophysical cascade which culminates in a change in cellular activity. Pharmacologists have studied these effects using log-dose response curves to illustrate these mechanisms. Whereas the X-axis represents increasing concentrations or amounts of an endogenous hormone, neurotransmitter, or chemical, the Y-axis measures the percentage of response elicited by the endogenous substance (Figure 1).

Partial agonists are drugs that bind and elicit partial (ceiling) responses, always less than the maximal efficacy of a full agonist. Partial agonists have duality of action: when alone, increasing doses cause more and more response with eventually the ceiling effect being reached; but when acting together with a full agonist, they can behave as an antagonist (blocker), never fully antagonizing, but displacing the full responses of the agonist and replacing them with the lesser efficacies of their ceiling effect (Figure 2).

Potency finally is a comparative measure. It is used to compare the doses required to reach a particular size effect: the most potent agonist is the one for which the smallest dose was given for the required response. Potency is often related to affinity, with the drug having the greatest affinity also having the highest potency.

Antagonism and Potentiation

Drugs interact with cellular responses in two distinct ways: inhibiting by antagonizing the process or augmenting by

Figure 1 Log-dose response curves. (a) Increasing concentrations of a full agonist along the X-axis increase responses to a maximum, read on the Y-axis. (b) Increasing concentrations of an antagonist block responses.

Figure 2 Duality of partial agonists. Partial agonists alone behave as agonists but have a ceiling effect (less than maximal response; bottom curve). In the presence of a full agonist response, increasing concentrations of partial agonists will antagonize the full response until the lesser ceiling effect is reached (top curve).

potentiating the responses. On a log-dose response curve, the curve labeled 'control' is obtained by increasing the concentration of the endogenous substrate alone and measuring the increasing responses. Potentiation is illustrated as a left-shift of the curve: essentially, one needs less of the endogenous chemical to elicit the responses, as if now the endogenous compound is more potent (benzodiazepines, which are sedatives/hypnotics potentiate gamma-aminobutyric acid (GABA), the major inhibitory transmitter in the human brain, e.g., while cocaine, a stimulant, potentiates norepinephrine, the major mediator of cardiovascular and stimulant responses). Antagonism is represented by a right shift of the curve. There are two types of pharmacological antagonism. When the antagonist competes with the endogenous agonist substance for binding (i.e., both recognize the same site on the receptor), increasing the concentration of the endogenous chemical will eventually

displace the blocking drug and reinstate the full efficacy, albeit with higher concentrations needed (hence the shift to the right). Most blockers act in this manner and are called competitive antagonists. In some cases, the antagonist may bind to a different site (allosteric binding) or may create a covalent or other strong bond at the binding site. In this case, increasing the concentrations or amount of the endogenous substance fails to fully recover the responses, and the curve is still shifted to the right but never reaches the maximum efficacy. Few drugs act irreversibly, since this property would result in unsafe effects that cannot be overturned easily. Finally, although pharmacological antagonism is classic, one cannot rule out physiological antagonism (Figure 3).

Physiological antagonism occurs when two agonists are administered, each having an opposing action: a bronchodilator and a bronchoconstrictor, for example, effectively resulting in canceling each other's effect. In rare instances, chemicals may also antagonize themselves simply by binding to each other, as in heparin's anticoagulant effect being antagonized by the antidote protamine sulfate.

Signal Transduction

Receptors are found in two broad locations: on the cell membrane or inside the cell.

Intracellular Receptors

Intracellular receptors are generally reserved for highly lipid-soluble drugs such as anti-inflammatory steroids, thyroid hormones, and vitamin A or D. These receptors belong to a superfamily of DNA-binding proteins. When activated by the binding of an agonist, they translocate to the nucleus of the cell and recognize specific binding sites along the chromosomal DNA called response elements. These DNA-binding sites are not part of genes in that they are not expressed. Rather, these DNA-binding sites are scattered along spacer DNA (the DNA between genes), and when activated, they can alter the patterns

Figure 3 Antagonism and potentiation. The control curve is obtained from a full agonist alone. All other curves are the full agonist in presence of another drug. When the curve is to the right of the control, more agonist is needed for the responses to occur: that is, an antagonist was added. When the curve is to the left of the control, less agonist is needed for the responses to occur: that is, a potentiator was added. Note that there are two forms of antagonism, competitive and noncompetitive.

of gene expression. Drugs that control gene expression not only have a slow onset of action (it can take hours or days to see the protein products) but also have a much longer duration of action, likely lasting beyond the drug's presence in the body. These receptors have specific structural elements to recognize on the one hand, the drug, and the DNA spacer elements on the other. Classic structures allowing DNA binding include zinc finger motifs, leucine zippers, helix-turn-helix, Rev domains, and many others. One can understand these intracellular receptors as specialized transcription factors that control as to when, where, and how much a specific gene or set of related genes will be expressed. Examples include the binding to peroxisome proliferator-activated receptors by thiazolidinediones (e.g., rosiglitazone) and fibrates (e.g., gemfibrozil) in the management of diabetes and hyperlipidemia, respectively. In the case of fibrates, the induction of lipoprotein lipase (LPL) activity (induction meaning more LPL enzyme is expressed by the cell in contrast to activation meaning greater affinity of existing LPL enzymes) is responsible for the digestion of endogenous and exogenous lipoproteins and the removal of triglycerides from the patient's blood (Figure 4).

Membrane-Bound Receptors

Ion channels

Membrane-bound receptors include the family of ion channels. Ion channels can be classified as gated and ungated. And gated ion channels fall in two major families: voltage and ligand gated. Conductance is the term reflecting the number of channels opened. Whereas ungated channels always have maximal conductance, gated channels require a change in membrane potential (mV) or a ligand binding to be opened. When a channel is open, ions may flow through the channel pore, called an ionophore, provided a net force is exerted on that ion (i.e., the ion is not at equilibrium). The net force is a combination of

concentration force (ions flow down a concentration gradient) and electrical force (opposite charges attract each other, and same charges repel each other). Changes in mV result from the movement of charged ions across the membrane. In general, cells have a resting potential more negative than that of the extracellular medium. Excitation follows depolarization, that is, the cells become more positive (positive ions like sodium going in or positive charges like potassium not leaving the cell); inhibition follows hyperpolarization, that is, the cells become more negative (negative ions like chloride going in or positive charges like potassium leaving the cell). mV changes are extremely rapid and can result in responses elicited within milliseconds. Ungated channels are the targets of certain diuretics (amiloride, triamterene). Voltage-dependent channels are blocked by a variety of antiseizure and antiarrhythmic medications (phenytoin, carbamazepine and quinidine, lidocaine, amiodarone, verapamil for a few examples). Ligand-gated channels include nicotinic acetylcholine receptors of the neuromuscular junction (blocked by curare-like drugs), those of neuronal tissues (stimulated by nicotine), GABA receptors (potentiated by benzodiazepines, prolonged in their opening by barbiturates or alcohol), several glutamate receptors (N-Methyl-D-aspartate and felbamate or ketamine, phencyclidine blocking it; 2-amino-3-(5-methyl-3-oxo-1,2-oxazol-4-yl) propanoic acid and topiramate), serotonin 5HT₃ receptors (blocked by the antiemetic ondansetron), and more (Figure 5).

G-protein-coupled receptors

The classic G-protein-coupled receptor (GPCR) remains the best characterized and most common signal transduction system. The human genome has close to a 1000 genes coding for GPCRs. Ultrastructurally, the presence of seven-transmembrane domains defines GPCR. While a drug binds to the outside segments of the receptor, the resulting change in

Figure 4 Intracellular receptors. Once stimulated by lipid-soluble ligands, intracellular receptors translocate to the nucleus and bind to response elements of the spacer DNA, altering the rate of gene expression. +1 represents the transcription start. An example would be steroid receptors binding to HRE (hormone response elements), through zinc finger motifs, allowing a steroid response to occur.

Figure 5 Ion channels. Ion channels allow charged particles to change the membrane potential. If the ion flow results in more positive potentials, the cell is depolarized and excited (cations entering or anions leaving a cell). Conversely, if the ion flow results in more negative potentials, the cell is hyperpolarized and less excitable (anions entering or cations leaving the cell).

shape activates a guanosine-5'-triphosphate (GTP)-binding protein coupled to the receptor on the inside face of the cell. G-proteins are trimeric, comprising alpha, beta, and gamma subunits. It is the alpha subunit that has a GTPase activity, and when GTP is 'burnt' to guanosine-5'-diphosphate (GDP), the G-protein transmits downstream the signal of a drug binding to the receptor outside of the cell. They function as switches to turn on or off enzymes, open or close ion channels, controlling transporters, transcription factors, and other targets of the cell's machinery. Although the alpha subunit seems the most

important in transmitting signals, the beta-gamma subunits are increasingly recognized as having their own roles (such as controlling potassium channels). Two major pathways are used by many of the drugs prescribed in medicine: the cyclic adenosine-5'-monophosphate (cAMP) pathway and the PIP_2 pathway (Figure 6).

The pattern followed includes a five-step transduction, starting with the binding of a drug to a GPCR. A G-protein is activated. It stimulates (Gs, Gq) or inhibits (Gi) an enzyme. The enzyme makes more or less of a 'second messenger,' such as cAMP or from a membrane phospholipid like PIP_2 , inositol trisphosphate (IP_3), and diacylglycerol (DAG). The second messenger is a metabolite that in turn controls the activity of a family of phosphorylating enzymes called serine/threonine kinases (protein kinase A in the cAMP cascade and protein kinase C in the PIP_2 cascade). When kinases phosphorylate substrates, they alter their activity. For example, an enzyme may be activated or inhibited by phosphorylation and an ion channel may be closed or opened. Interestingly, receptors localized on the same cell may well modulate the cellular activity through coupling to opposite G-proteins. Whereas Gs coupling would increase cAMP and result in phosphorylation by protein kinase A of effector proteins, a Gi-coupled receptor would undo this effect by decreasing cAMP in the same cell. An example would be norepinephrine stimulating the Gs coupling of its β_1 receptor, causing an increased firing rate and conduction of electrical potential in selective heart tissue, whereas acetylcholine through its Gi-coupled muscarinic M_2 receptors does the opposite. The resulting effects are an increased heart rate in the presence of sympathetic stimulation of the heart (mediated by norepinephrine) and a decreased heart rate from parasympathetic stimulation of the heart (mediated by acetylcholine). Major pharmacological systems follow this pattern. In particular, catecholamine (dopamine, norepinephrine, and epinephrine) receptors, muscarinic

Figure 6 G-protein-coupled receptors. These receptors interact with G-proteins (Gs, Gi, and Gq) to alter second messenger levels and protein kinase activity in the cell. Phosphorylation alters the activity of select enzymes, receptors, channels, transcription factors, structural proteins, and so on. Phosphatases return the target proteins to their initial state.

Table 1 Receptor subtypes to select ligands and their G-protein coupling. Gs stimulates adenylyl cyclase and raises intracellular levels of cAMP, whereas Gi inhibits adenylyl cyclase and decreases cAMP concentrations. Gq stimulates phospholipase C and increases intracellular IP₃, DAG, and calcium

Ligand	Receptor	Mechanism
Epi, norepinephrine	α_1	Gq
	α_2	Gi
	$\beta_{1,2}$ (Epi only)	Gs
Acetylcholine	M _{1,3,5}	Gq
	M _{2,4}	Gi
Dopamine	D _{1a,b}	Gs
	D _{2a,b,c}	Gi
Serotonin	5HT _{1,5}	Gi
	5HT ₂	Gq
	5HT _{4,6,7}	Gs
Glutamate	mGluR _{1,5}	Gq
	mGluR _{2,3,4,6,7,8}	Gi
GABA	GABA _B	Gi
Opioid peptides	μ , κ , δ	Gi
Cannabinoids	CB _{1, 2}	Gi

receptors to acetylcholine, six out of seven subtypes of serotonin receptors, many hormonal receptors (thyroid stimulating hormone, antidiuretic hormone, V₂ receptors, parathyroid hormone), metabotropic glutamate receptors, and GABA_B receptors, all have in common this signal transduction pattern involving a seven-transmembrane receptor, a G-protein, an enzyme, a second messenger, and a kinase (Table 1).

Other transduction systems may in part mimic that of the classic GPCRs. An example is the pathways involving cGMP. In one instance, the receptor to atrial natriuretic factor (ANF) (stimulated by the drug nesiritide used in congestive heart failure) has the activity of the enzyme guanylate cyclase. Its stimulation by the endogenous atrial natriuretic peptide or the recombinant drug nesiritide immediately results in the

formation of the second messenger cGMP and the subsequent activation of protein kinase G, resulting in a phosphatase activation and the dephosphorylation of the contractile protein myosin light chain with resulting vasodilation. But more relevantly, in another variation on the pathway, arginine is metabolized by nitric oxide synthase in the endothelium of the vasculature, causing the release of NO, a gas, which diffuses to the adjacent smooth muscle cell and directly binds the heme groups of a soluble guanylate cyclase, resulting in the formation of cGMP and, similar to ANF, the relaxation of smooth muscle. Many cardiovascular drugs share that pathway: nitric oxide donors, such as the antianginal nitrates, the antihypertensive nitroprusside, and hydralazine, are prodrugs of NO. Others may bind to Gq-coupled receptors on the endothelium, resulting in the activation of NO synthase (muscarinic M₃, histamine H₁, prostaglandins, and leukotrienes, and certain serotonin receptors). Finally, drugs may result in increased cGMP by preventing its breakdown by phosphodiesterases; for example, the PDE-type V inhibitors, used in erectile dysfunctions or pulmonary hypertension, exemplified by sildenafil (Figure 7).

Enzymes as receptors

Several classes of drugs bind to enzymes and directly control their activity. Acetylcholinesterase is the main mode of degradation of the neurotransmitter acetylcholine once released in the synapse. Its inhibition by organophosphate or carbamate insecticides will result in dramatic increase in synaptic acetylcholine and overstimulation of muscarinic and nicotinic receptors with ensuing life-threatening toxicity. It is also the target of drugs like neostigmine, used to reverse neuromuscular blockade from curare-like drugs, diagnose or treat myasthenia gravis, or reverse the toxic overdose of antimuscarinic drugs like atropine. Another example would be the nonsteroidal anti-inflammatory drugs like aspirin inhibiting the enzyme cyclooxygenase and the production of inflammatory prostaglandins and the platelet aggregant thromboxane A₂. The blockade of angiotensin-converting enzyme (ACE) by captopril and other

Figure 7 Nitric oxide (NO) signaling cascade. The activity of nitric oxide synthase (NOS) is controlled by Gq-coupled receptors on the endothelium of vessels (e.g., acetylcholine (ACh) M_3 receptors, serotonin (5HT) $5HT_2$, and receptors). The NO produced diffuses to the adjacent smooth muscle cells and causes relaxation and vasodilation through increased levels of cGMP. Many drugs interfere with this pathway. PDE, phosphodiesterase.

ACE inhibitors allows better management of diabetic nephropathies and congestive heart failure patients while managing millions of hypertensive patients around the world.

Transporters as receptors

Transporters are transmembrane proteins specialized in carrying substrates from one side of the cell membrane to the other. Reuptake pumps are a relevant example of transporters. Reuptake is the removal of neurotransmitter molecules from the synaptic cleft back into the nerve terminal that released them. It is the main mode of termination of action for norepinephrine in the periphery, dopamine, and serotonin. Antidepressants and cocaine owe some of their pharmacological effects to the blockade of reuptake, resulting in prolonged presence of neurotransmitters in the synapse and longer stimulation of receptors on effector cells. Amphetamines in part reverse the pumping mechanism and cause the release of the mobile pool of neurotransmitters back in the synapse (the mobile pool represents the nonvesicular neurotransmitter that was freshly reuptaken but not yet repackaged into synaptic vesicles).

Receptors with intrinsic enzymatic activity

As discussed previously, this class of receptors includes the ANF receptor, which has guanylate cyclase activity. But it also encompasses the large family of receptors that have tyrosine kinase activity. Tyrosine kinase distinguishes itself from the other classes of serine/threonine kinases such as protein kinases A, C, and G. It is intrinsic to the receptor, and as its name indicates, the activation of the receptor results in the phosphorylation of tyrosine residues, first on the receptor itself, and then on a number of effector proteins. Insulin receptors belong to this group. The activation of the receptor by insulin triggers a signal transduction system that is drastically different from the one shared by GPCRs. In particular, the final element often involves phosphatases that can dephosphorylate proteins

previously phosphorylated by kinases, thereby offering a modulation in cellular activity. For example, glucagon and epinephrine oppose insulin on most metabolic responses. Whereas glucagon and epinephrine share a G_s -coupled mechanism through their respective receptors, which causes effector enzymes to be phosphorylated, insulin results in the dephosphorylation of the same enzymes, causing the opposite activity. Most growth factors and cytokines bind to receptors with intrinsic tyrosine kinase activity. For cytokine receptors, the tyrosine kinase is referred to as a Janus kinase (JAK), and its substrate is transcription factors called STAT (signal transducer and activator of transcription). A number of cancers share abnormal signaling involving these tyrosine kinases. A class of anticancer drugs, such as imatinib for chronic myelogenous leukemia and erlotinib for certain types of lung cancers, actually aims at blocking tyrosine kinases.

Tolerance and Dependence

Receptor Adaptation and Tolerance

Continuous presence of a drug can result in a blunting of the responses over time in spite of the presence of the drug. In the case of GPCRs discussed previously, receptor regulation can result in rapid fluctuation in responsiveness. Two key words are used to describe changes in the receptor function: sensitization/desensitization and up/downregulation. Whereas sensitization/desensitization is a rapid change in affinity of existing receptors in the membranes of cells, up- and downregulation reflect changes in the number of receptors in the cell membrane. Intuitively, agonists could result in desensitization or downregulation, whereas antagonists would result in sensitization or upregulation. The process remarkably results in a loss of efficacy of the drugs administered. If the process is very rapid, acute tolerance is sometimes referred to as tachyphylaxis. The mechanism of rapid desensitization of β receptors

(and many other GPCRs) involves phosphorylation of the receptor itself by a G-protein-coupled receptor kinase called GRK. When agonists bind to the receptors, they activate GRKs, which in turn phosphorylate the receptors themselves. The phosphorylated serine residues then bind to beta-arrestin, which prevents the interaction of the receptors with their respective G-protein, thereby stopping the signaling cascade. Upon removal of the agonist, phosphatases 'reactivate' the receptors: subsequent administration of the agonist results in responses similar to the initial ones (i.e., desensitization is a reversible process). A more prolonged effect is the endocytosis of the receptors, also mediated in part by β -arrestin. Endocytosed receptors can be reversed unless the engulfed receptors are targeted to lysosomes where they would be degraded, effectively decreasing the responses of an agonist for a prolonged period of time.

Compensatory Responses and Drug Tolerance

Rather than changes in the receptors themselves, changes distal to the receptor in transduction can result in tolerance. These changes tend to be mediated by other systems available to the cell or organism in order to oppose the action of a drug. For instance, opiates result in a tolerance not readily explained by changes in opiate receptor function or number but rather by changes in the second messenger cAMP. Whereas opiate receptors are all G_i coupled and their stimulation results in a decreased intracellular cAMP level, in tolerant cells, increased cAMP levels are seen, likely mediated by other receptor system compensating for the continuous inhibitory influence of the opiate drug. Tolerance to central nervous system (CNS) depressants in general is well established, often with cross-tolerance between drugs acting in similar ways (such as benzodiazepines, barbiturates, and ethanol). But tolerance is not seen with CNS drugs alone. Drugs acting peripherally can also exhibit tolerance. An example is the homeostatic responses elicited by drugs that alter blood pressure: antihypertensives trigger autonomic and endocrine responses aimed at antagonizing the antihypertensive effect of the drug administered. As blood pressure drops, sympathetic responses alter hemodynamic parameters such as heart rate and contractility of the heart muscle and blood vessel tones through baroreceptor reflexes, while the renin-angiotensin-aldosterone system regulates not only the blood vessel tone but also the blood volume. Increased sympathetic and renin activity act in concert to increase the blood pressure back to initial baseline in spite of the antihypertensive drug's presence. This explains the need for several drugs, including beta blockers and diuretics in most cases, in the management of hypertension to maintain the antihypertensive effect of the primary drug (Figure 8).

Reduced Availability of Response Mediators

In a similar way, reduced availability of response mediators can result in tolerance. A classic example involves the amphetamines or the food amine tyramine which owes its action to the release of neurotransmitters from its mobile pool in the nerve terminal. Once the pool is exhausted (i.e., completely released), administration of more amphetamine cannot elicit

Figure 8 Tolerance and withdrawal.

further responses. Another example is represented by the tachyphylaxis to nitrates used in ischemic heart disease management. Nitroglycerin is a prodrug of NO which requires the presence of glutathione in its activation. The finite stores of glutathione can result in depletion if the drug is used too often. Once depleted, the nitrates can no longer be activated.

Metabolic Tolerance

Another mode of tolerance is metabolic rather than pharmacodynamic: induction of the microsomal oxidizing system of cytochrome P450 enzymes can result in a more rapid metabolic clearance of a drug, requiring larger doses to get the same effect. For instance, barbiturates and carbamazepine can induce their own metabolism, resulting in decreased duration of action and requiring greater doses to achieve a similar depressant effect. Chronic ethanol also induces metabolic tolerance.

Behavioral Factors

Behavioral factors also contribute to tolerance and dependence. Animal studies have shown that tolerance can be altered by varying the experimental conditions, such as time of administration and prior experiences of the test animal. Similarly, environmental cues are known to trigger withdrawal in human addicts if withdrawal was previously experienced under such conditions.

Dependence

Dependence is characterized by overt symptoms on withdrawal of the drug, resulting in physical symptoms or psychological changes (craving). The assumption has been that the same mechanisms responsible for tolerance are also fundamentally responsible for dependence on the drug. Altered sensitivity or numbers of receptors, changes in other receptors, increased activity of enzymes, and compensatory mechanisms predict that tolerance and dependence are associated processes. Dependence would require the presence of adaptive changes induced by the drug causing tolerance. Yet, it is also evident that some of the mechanisms causing tolerance are not

necessarily associated with dependence: the rapid phosphorylation of beta receptors caused tolerance to an agonist, but its rapid dephosphorylation upon agonist withdrawal reset the receptor to normal, for example. The duration of changes elicited by the drug presence is important: if they exceed the drug's presence, then dependence will likely result from withdrawal of the drug.

Conclusions

Several hundreds if not thousands of discrete intracellular and extracellular receptors recognize endogenous and exogenous molecules. In spite of this evergrowing variety, general patterns of signal transduction underlying the mechanisms of action of drugs have emerged. These pathways are responsible for amplifying the biochemical and physical responses of the various subtypes of cells and tissues making the human body in a cell-dependent manner. An important aspect of having a far greater number of receptor types than pathways is the potential for pharmacodynamic interactions between drugs of different structure and different pharmacological profile. An interesting concluding note would relate this possibility well. In the case of beta blocker overdose, rather than a beta agonist, glucagon is administered. Both beta receptors and glucagon receptors share Gs coupling and have similar tissue distribution allowing a hormone to undo the detrimental effects of a cardiac drug through its action on a different type of receptor. Whereas more immediate responses from cellular events are well

established, recent advances and emphasis on DNA machinery, its plasticity, and gene expression control will undoubtedly contribute to even greater, potential understanding of drug action, in particular when it relates to chronic effects, and mechanisms of tolerance and dependence.

Glossary

Analytical toxicology The use of analytical methods to detect substances.

Confirmation test The second test or the test that unequivocally identifies a substance.

Exhibit Applies to both specimens and physical items such as tablets and syringes.

Forensic toxicology Application of toxicology to meet the needs of the courts.

Quality assurance A process that checks the reliability of a laboratory to conduct its work.

Receptor Specific recognition site in tissues that is usually functionally connected to a physiological response.

Screening test The initial test that suggests the presence of a substance or class of substances.

Toxicology The science of poisons.

Introduction

Toxicology when used in a forensic capacity involves the analysis of specimens and other exhibits for chemical substances in cases involving an investigation that has the potential to go before a court of enquiry. This distinction to an ordinary analytical toxicologist is important, since a conventional toxicologist is mainly concerned with the detection of substances and may not understand the specific medico-legal requirements in forensic cases.

These chemical substances cover a wide variety of drugs and poisons and require the use of a variety of analytical techniques. These techniques, when used together, are able to provide sufficient coverage of possible substances to exclude relevant drugs and poisons, and when a substance(s) is detected, the analytical proof is sufficient to meet the needs of the law.

This article outlines the applications of this discipline, the techniques used, and how they are best applied and monitored in forensic cases.

Applications of Forensic Toxicology

Forensic toxicology has a number of applications. It plays an essential role in death investigations by providing investigators with information on whether the use of substances is relevant to the cause and manner of death. The request to perform 'toxicology' may be based on information on the possible use of chemical substances (including prescribed drugs), or it may simply be requested to exclude the involvement of substances that either have a bearing on the cause of death or may have affected the behavior of the person. The latter is most important in the investigation of vehicular crashes, where substance use may have affected the ability to drive safely and therefore contributed to the event. In some cases, a suspected use of psychoactive drugs, particularly alcohol and the common drugs of abuse (amphetamines, cocaine, cannabis, benzodiazepines, etc.), in a murder is commonly encountered. While these drugs may not have caused the death, their presence indicates the use of drugs (and perhaps other substances)

either for health reasons and/or for recreational purpose. In many cases, abuse of drugs leads to significant behavioral changes that can lead to criminal acts or expose them to increased vulnerability to be a victim of a crime.

Toxicology testing is also important in victims of crime or in persons apprehended for a crime. Drugs may have been given by the assailant to reduce consciousness of the victim, as in rape cases. These drugs include the benzodiazepines and related sedatives and hypnotics (e.g., alprazolam and zolpidem) and gamma-hydroxybutyrate (GHB). Toxicology also establishes if any drug was used by the victim that may have affected consciousness or behavior. Defendants arrested shortly after allegedly committing a violent crime may be under the influence of drugs. It is vital, therefore, that toxicology testing is conducted (on relevant specimens) to establish the extent of drug use, since allegations of drug use and its effect on intent or clinical state may be raised in legal proceedings.

Forensic toxicology is also used in employment drug testing and in human performance testing. The former category relates to the detection of drugs of abuse in persons in a place of employment, prior to being hired by an employer, or even a person in detention, such as the one in a prison. Human performance testing relates to the detection of drugs that might have increased (usually) performance in athletic events. This may even apply to animals, such as horses, and jockeys that ride them. Specimens used in these cases are usually urine, although hair can be used to provide a longer window of detection.

Initial Tests and Confirmation

The foremost goal in forensic toxicology is the need to provide unequivocal proof of the presence of a substance(s). The use of conventional techniques that do not provide proof of structure (e.g., gas chromatography, GC; thin layer chromatography, TLC; and high-performance liquid chromatography, HPLC) would not normally be sufficient to provide unequivocal proof of the presence of a chemical substance when used alone. Two or more independent tests are normally required, or the use of a more powerful analytical test, such as mass

Figure 1 Schema showing identification, confirmation, and quantification processes in forensic toxicology.

spectrometry (MS), is expected. Because of the need to perform a rigorous analysis, the analytical schema is often broken up into two steps. The identification stage is termed the screening or initial test, while the second analytical test is the confirmation process. The confirmation process often also provides a quantitative measure of how much substance was present in the sample; else, a separate test is required to quantify the amount of substance present in the specimen. In all processes, it is important that no significant analytical inconsistency appears, or else a result may be invalidated (Figure 1).

For example, in the identification of codeine in a blood specimen, an immunoassay positive to opiates is expected to be positive for codeine in the confirmation assay. The apparent detection of a drug in one analytical assay but not in another means that the drug is not confirmed, provided that both assays are capable of detecting this drug. Table 1 provides a listing of common techniques used in screening and confirmation assays.

While MS is the preferred technique for confirmation of drugs and poisons, some substances display poor mass spectral definition. Compounds with base ions at mass/charge ratios of <100, or with common ions with ratios such as m/z 105, and with little or no ions in the higher mass range are not recommended for confirmation by MS alone. Derivatization of a functional group to produce improved mass spectral properties can often be successful. Common derivatives include per-flouroacyl esters, trimethyl silyl ethers, and so on. Alternatively, reliance on other chromatographic procedures can provide

Table 1 Screening and confirmation techniques

Screening tests	Confirmation tests
Immunoassays (various)	MS (LC, GC, CE) including tandem MS
Spectroscopy (UV, F, etc.)	TOF-MS and other forms of high-resolution MS
HPLC (UV, F, ECD, CD)	Second chromatographic test
GC (FID, NPD, TD)	AAS and ICP-MS
TOF-MS and other forms of high-resolution MS	
CE (UV, F)	
AAS, colorimetric tests	

UV, ultraviolet; F, fluorescence; ECD, electrochemical detection; CD, conductivity detection; HPLC, high-performance liquid chromatography; GC, gas chromatography; FID, flame ionization detector; NPD, nitrogen phosphorous detector; TD, thermionic detector; CE, capillary electrophoresis; AAS, atomic absorption spectroscopy; ICP-MS, inductively coupled plasma MS; MS, mass spectroscopy; DAD, photodiode array detector; TOF, time of flight.

adequate confirmation. It is important when using any chromatographic procedure (e.g., HPLC and GC) that the retention time of the substance being identified matches with that of an authentic standard. Criteria exist for retention time variability and for acceptance of mass spectral information.

Some apparent analytical inconsistencies may provide important forensic information. For example, if a result for opiates is negative in urine, but positive in blood, it is possible that heroin was administered shortly before death (heroin is rapidly metabolized to 6-acetylmorphine and morphine), and therefore metabolites had not yet been excreted. This situation is often found in heroin users dying from an acute sudden death in which substantial urinary excretion has not yet occurred.

Common Drugs and Poisons

The most common drugs and poisons are clearly the initial targets of any forensic toxicological analysis, particularly if no specific information is available to direct the investigation. The most common substances can be categorized as fitting into four classes, for example, alcohol (ethanol), illicit drugs, licit (ethical) drugs, and the nondrug poisons.

The most common substances detected in forensic toxicology laboratories are shown in Table 2. The types of substances are likely to be similar throughout developed countries, although significant regional variations can occur depending on the local availability of drugs. Herbal remedies are widely available; in some situations, these can be dangerous if mixed with pharmaceutical or illicit drugs, and in some cases, drugs are illegally added to enhance the effects of the preparation.

Alcohol is the most frequent detection in many countries, and when detected, it can play an important role in any investigation because of its ability to depress the central nervous system (CNS). At best, alcohol will modify behavior, causing disinhibition and possible aggression; at worst, it can cause death, either by itself or in combination with another substance.

Table 2 Most common drugs of interest in forensic toxicology

Ethanol (alcohol) ^a	
Amphetamines	Amphetamine, methamphetamine, MDMA, MDA, MDEA, etc.
Analgesics and anti-inflammatories	Acetaminophen (paracetamol), salicylate, NSAIDs, etc.
Anticonvulsants	Carbamazepine, lamotrigine, phenytoin, valproate, etc.
Antidepressants	(es)Citalopram, fluoxetine, venlafaxine, paroxetine, amitriptyline, etc.
Antipsychotics	Olanzapine, haloperidol, clozapine, etc.
Benzodiazepines	Alprazolam, clonazepam, diazepam, temazepam, oxazepam, etc.
Cannabis	Δ ⁹ -Tetrahydrocannabinol and metabolites
Cocaine and metabolites	
Opiates	Morphine, heroin, codeine, hydromorphone, oxycodone, etc.
Opioids ^b	Methadone, meperidine, fentanyl, etc.
Muscle relaxants	Carisoprodol, dantrolene, orphenadrine, etc.
Other hypnotics	Zolpidem, zopiclone, etc.

MDMA, 3,4-methylenedioxy-methamphetamine; MDA, 3,4-methylenedioxy-amphetamine; MDEA, 3,4-methylenedioxy-ethylamphetamine; NSAID, nonsteroidal anti-inflammatory drugs such as ibuprofen, naproxen, etc.; THC, Δ⁹-Tetrahydrocannabinol.

^aThis list is alphabetical after ethanol. There will be substantial variation in the incidence of these substances from one jurisdiction to another. Only the more common examples of each drug type are included as examples.

^bThese are synthetic drugs acting like the opiate drugs.

Illicit drugs most commonly include the amphetamines, cocaine, cannabis, heroin, and other opiates/opioids. In some jurisdictions, GHB, ketamine, phencyclidine, and fentanyl are available as illicit substances. Designer drugs based on existing illicit drugs are increasingly becoming available. These have included analogs of amphetamine and methamphetamine, often branded as ecstasy (3,4-methylenedioxy-methamphetamine, 3,4-methylenedioxy-ethylamphetamine, etc.), but now include a variety of other synthetic substances. Those that mimic the action of tetrahydrocannabinol (THC) have been given names such as Spice and Kronic. A series of stimulants that act like the amphetamines include the piperazines, phenethylamines, 4-substituted amphetamines, β-keto-amphetamines, 2,5-dimethoxy-amphetamines, pyrrolidinophenones, and analogs of cathinone (derived from Khat) that include mephedrone.

It should be borne in mind that some illicit drugs also have medical uses in some countries. Cocaine is used in some forms of facial and nasal surgery, (dex)amphetamine is used to treat narcolepsy and attention deficit syndrome, and cannabis (as the active form THC and other cannabinoids) is used (among other indications) to reduce nausea following chemotherapy. Benzodiazepines are widely prescribed to relieve anxiety and induce sleep among other indications but are also widely abused, often with the illicit substances.

Ethical drugs include the whole range of prescription and over-the-counter drugs used in the treatment of minor to major ailments. Those of most interest include the antidepressants, antipsychotic drugs, narcotic analgesics and other forms of pain relievers, and anticonvulsants. Since these drugs are widely prescribed, they are by far the most commonly encountered drugs in toxicology. Each country will have its own list of

Table 3 Most common (nondrug) poisons of interest in forensic toxicology

Alcohols (other than legal ethanol; e.g., methanol) ^a
Aliphatic hydrocarbons (methane, LPG, butane, and petroleum products)
Aromatic hydrocarbons (toluene, xylene, etc.)
Carbon monoxide (from automobile exhausts and fires)
Cyanide (as salt or derived from burning fuels forming hydrogen cyanide)
Ethylene glycol
Inorganics (salts of arsenic, lead, mercury, thallium, etc.)
Pesticides (chlorpyrifos, carbofuran, aldicarb, etc.)
Other agricultural chemicals (paraquat, diquat, 2,4-D, glyphosate, etc.)
Plant-derived poisons (scopolamine, digoxin-like glycosides, etc.)
Potassium (from legal preparations often as chloride)
Solvents (toluene, chloroform, ethers, etc.)
Strychnine and other rodenticides
Warfarin and other anticoagulants (e.g., brodifacoum)

2,4-D, 2,4-dichlorophenoxyacetic acid; LPG, liquid petroleum gas.

^aThis list is alphabetical. There will be substantial variation in the incidence of these substances from one jurisdiction to another. Only the more common examples of each are included as examples.

registered drugs; hence, laboratories will need to consider these as a matter of priority over other members of a particular class available elsewhere. From time to time, laboratories will be required to consider drugs that are not legally available in their countries because of illicit supplies or supplies through tourists visiting their country.

The nondrug poisons most commonly include organophosphates and other pesticides, carbon monoxide and hydrogen cyanide derived from burning materials in fires, cyanide salts, and volatile substances (petrol, natural gas, kerosene, etc.). Other poisons include the metals and their salts (arsenic, mercury, thallium, etc.), plant-derived poisons (hyoscyne from belladonna species, coniine from hemlock, etc.), strychnine, and toxins such as venoms. Performance-enhancing drugs such as the anabolic steroids may also be considered in some instances. Clearly, this list is potentially unending, although some chemicals are more readily available to certain occupational groups than others and are dependent on national regulations within countries. The most common poisons are shown in Table 3. Clearly, the distribution of unusual substances will vary from country to country.

Scope of Testing Protocols

As the previous sections indicate, cases may involve a variety of ethical and illicit drugs or unusual poisons. Worldwide experience also shows that forensic cases often involve more than one drug substance. A survey of drug-related deaths shows that three or more drugs are present in >70% of cases. High rates of multiple drug use are also found in perpetrators and victims of violent crimes, suicides, and often also in accidents and road crashes.

It is also well known by forensic toxicologists that the information provided to the laboratory concerning possible drug use may not accord with what is actually detected. It is therefore strongly recommended that laboratories provide a systematic approach to their toxicology cases and include as

wide a range of common ethical and illicit drugs as feasible. This approach is termed systematic toxicology analysis. A laboratory using this approach would normally include a range of screening methods often incorporating both chromatographic and immunological techniques. Drug classes such as alcohol, analgesics, opioid and nonopioid narcotics, amphetamines, antidepressants, benzodiazepines, barbiturates, cannabis, cocaine, antipsychotic drugs, and other CNS-depressant drugs would be included.

The incorporation of a reasonably complete range of drugs in any testing protocol is important, since many of these drugs are mood altering and can therefore affect behavior, as well as affect the health status of an individual. Persons using benzodiazepines, for example, will be further affected by cocaine, amphetamine use, and use of other CNS-depressant drugs. The toxic concentrations of drugs are also influenced by the presence of other potential toxic drugs. For example, the fatal dose of heroin is affected by the concomitant use of alcohol and other CNS-depressant drugs.

Specimens

It is essential that the relevant specimens are taken whenever possible, since recollection is rarely possible. In living persons, drugs and their metabolites will often not persist for more than several hours to days. The preferred specimens collected in forensic toxicology will of course depend on the nature of the case. In general, a blood specimen is a minimum requirement, although specimens such as urine can be useful for laboratories as a screening specimen and to check for the use of drugs two or more days prior to sampling.

Hair can provide even longer memory of drug intake, lasting up to several months, depending on the length of hair. Drugs are usually incorporated into the growing root matrix and are detected analytically as a band in the hair shaft when it externalizes from the skin. This process can therefore provide a history of when exposure to a drug or poison has occurred. Most drugs and poisons are incorporated into hair, although the extent will depend on the physiochemical properties of the substance. Basic drugs are often found in higher concentrations than acidic drugs, and invariably the parent drug is present rather than metabolites. For example, cocaine and the heroin metabolite 6-acetylmorphine are more likely to be found in the hair of cocaine and heroin users than their corresponding metabolites found in blood and urine (benzoylecgonine and morphine). Unfortunately, some drug will be absorbed into the hair from skin secretions adjacent to the hair follicles and may even be incorporated from external contamination. Care and treatment of hair, through processes such as washing and use of dyes and bleaches, will also affect the concentration of the drug in hair. Consequently, any interpretation of drug content in hair needs to factor these considerations.

Courts and other legal processes usually require proof that the laboratory has taken all reasonable precautions against unwanted tampering or alteration of the evidence. This applies to specimens and to physical exhibits used by the laboratory in their toxicology investigations. Consequently, it is essential that the correct identifying details are recorded on the exhibit

or specimen container, and an adequate record is kept of persons in possession of the exhibit(s). Alternatively, when couriers are used to transport exhibits, then the exhibit must be adequately sealed to prevent unauthorized tampering.

General Techniques

The range of techniques available for detection of drugs in the specimens collected for postmortem is essentially identical to those collected. These range from commercial kit-based immunoassays to instrumental separation techniques such as HPLC, GC, and capillary electrophoresis. MS is the definitive technique used to establish proof of structure of an unknown substance and is usually linked to either a GC or an HPLC. High-resolution MS, sometimes known as time-of-flight MS, is also increasingly being used to identify substances on the basis of their accurate molecular weight.

The use of appropriate extraction techniques is critical to all analytical methods. Three main types of extractions are used: liquid-liquid, solid-phase, and direct injection. Traditionally, liquid techniques, in which a blood or urine specimen is treated with a buffer of an appropriate pH followed by a solvent capable of partitioning the drug out of the matrix, have been favored. Solvents used include ethyl acetate, toluene, hexane, various alcohols, and butyl chloride, and mixtures thereof. The solvent is then isolated from the mixture and either cleaned up by another extraction process or evaporated to dryness.

Solid-phase techniques, particularly using mixed-phase supports, are commonly used in that they offer the ability to extract substances of widely differing polarity more readily than liquid-liquid techniques. Often, less solvent is used, or a simple hydro-alcoholic system can be employed, rather than potentially volatile or inflammable solvents.

Direct injection into either GC or HPLC instruments bypasses the extraction step and can offer a very rapid analytical process. In GC, solid-phase micro-extraction is most commonly used, while HPLC tends to require use of precolumns that are back-flushed with the use of column-switching valves.

Quality Assurance and Validation

An essential part of any form of toxicological testing is validation and the conduct of quality assurance. It is important that the method used is appropriately validated, that is, it has been shown to accurately and precisely detect the substance(s) detectable, that there is little or no interference (from other drugs and from the matrix) with the specimens used, and that a useful detection limit has been established. Moreover, it is essential that the method is rugged and will allow any suitably trained analyst to conduct the procedure and achieve the same results as those achieved by another analyst. To achieve these aims, it is necessary to trial the method in the laboratory over several assays with varying specimen quality before claiming that a full validation has been conducted.

It is recommended to include internal quality controls with each batch of samples to enable an internal check of the reliability of each assay. These controls contain known drugs

at known concentrations. Suitable acceptance criteria are required for these controls before results of unknown cases can be accepted and released to a client. Acceptance criteria vary depending on the analyte and application. For example, blood alcohol estimations have acceptance criteria of <5%, while postmortem blood procedures may be at 15%.

An important feature of analytical assays in forensic toxicology is the use of internal standards. These are drugs of similar chemical and physical characteristics as the drug(s) being analyzed, and when added at the start of the extraction procedure, they provide an ability to negate the effects of variable or low recoveries from the matrix. Hence, even when recoveries are low, the ratios of analyte and drug are essentially the same as those for situations of higher recovery. An ideal recovery marker is when the internal standard is a deuterated analog of the analyte. When deuterated internal standards are used, it may not be necessary to match the calibration standards with the same matrix as the unknown samples. It is important, however, that absolute recoveries are reasonable, that is, at least over 30%. This ensures less variability between samples and optimizes the detection limit.

From time to time, it will be important to run unknown samples prepared by another laboratory, or a person not directly involved in laboratory work, to establish proficiency. These are known as proficiency programs or quality assurance programs. These trials are often conducted with many other laboratories conducting similar work and provide an independent assessment of the proficiency of the laboratory to detect (and quantify) specific drugs. The performance of the laboratory should be regularly assessed from these results, and any corrective action should be implemented, if appropriate. This process provides a measure of continuous improvement, an essential characteristic of any laboratory.

There are a number of collaborative programs available throughout the world. The College of American Pathologists (CAP) organizes an excellent series of proficiency programs in forensic toxicology.

The International Association of Forensic Toxicologists (TIAFT) and American Society of Forensic Toxicology (SOFT) provide guidelines on the conduct of analytical assays and on quality assurance of assays.

Estimation of Dose

A common request from legal counsel and police is to estimate a dose from a blood or tissue concentration. This may relate to determining likely intent from an ingestion (or injection) or simply to rationalize the circumstances to specific amounts of drugs used.

While some practitioners attempt to calculate a dose, in reality there are so many variables that can affect this estimation that it is not possible except in rarest of circumstances. At best, a dose range may be estimated, but it must take into account unabsorbed drug, bioavailability, excreted drug, large variations from person to person in terms of the pharmacokinetics, possible accumulative effects of repeated doses, gender, age, and, in death investigations, the likely possibility of postmortem processes affecting the concentration of the substance.

Occasionally, it may be possible to compare blood (and tissue) concentrations to other cases in which doses were known by measuring the body burden in several tissues including muscle and fat. Analysis of gastric and intestinal drug content will assist in this process and may also provide information on the route and time of ingestion.

Interpretation of Toxicological Results

Interpretation of any toxicological result is complex. Consideration must be given to the circumstances of the case and, in particular, to the significance that may be drawn from the toxicology. For example, the finding of a drug in potentially toxic concentrations in a person killed by a gunshot wound to the head cannot reasonably lead to the conclusion that drugs caused the death. On the other hand, the absence of an obvious anatomical cause of death will lead investigators to consider the role of any substance detected in the analyses. Considerations must include the chronicity of drug use, the age of the person, the health of the person (presence of heart, liver, kidney disease, etc.), the use of multiple substances, and even genetic factors that may lead to altered metabolism.

Court Testimony

Forensic toxicologists and other analysts called in to give evidence in court should consider that much of their technical evidence is beyond the ready comprehension of lay people in juries, legal counsel, and judges. Restricting their evidence to understandable language and simple concepts is highly recommended.

A further problem relates to an assumption often made by legal counsel (and other parties) that a toxicological investigation was exhaustive and all drugs and poisons were tested for. Most toxicology performed is restricted to a few analytical tests for a range of 'common drugs and poisons' unless the client (e.g., a pathologist or police officer) has made a request to examine for (additional) specific chemicals. Analysts should make courts aware of the actual testing conducted and provide a list of substances incorporated in the investigation. Importantly, advice on any limitations applied to the interpretation of the analytical results, such as poor quality specimens, postmortem artifacts, and so on, should be provided. Above all, toxicologists must restrict their evidence to those areas in which they claim expertise. Testifying beyond their expertise or, worse, so as to favor one side in a case can lead to incorrect or misleading evidence and damage the reputation of the expert.

Drug Screening in Sport

L Rivier, Laurent Rivier Scientific Consulting, Lausanne, Switzerland

© 2013 Elsevier Ltd. All rights reserved.

Introduction

The fight against drug abuse in sports started around 1960 and was forced to improve over time on each occasion when new and more sophisticated pharmacological products or forbidden practices were discovered. Doping using drugs is proven first by means of state-of-the-art sports drug-testing assays and was sometimes substantiated by confessions of convicted athletes and results of searches by regulatory authorities. When novel drugs or methods of doping and manipulation become evident, the development of new, complementary, and more comprehensive doping control strategies is required. These strategies need to comply with strict forensic requirements as penalties for athletes can be severe and some of the prominent athletes easily mount legal challenges to the evidence.

What is Doping in Sport?

Besides stimulants and narcotics, anabolic agents, and peptide hormones, many substances are used and abused to improve the mental and/or physical performance of athletes. This is called doping and contradicts both sport and medical ethics. For the International Olympic Committee, the International Sport Federations, World Anti-Doping Agency (WADA), and all the national anti-doping organizations, doping is considered as cheating. The WADA Code defines precisely doping and its control in sport. The large majority of anti-doping testing programs endorse WADA regulations. Doping is considered an offense to the spirit of sport and is sanctioned by penalties as high as several years of suspension or exclusion to the practice of sport. The disciplinary authorities apply these important sanctions after the laboratory has reported an adverse analytical finding, that is, the presence of a forbidden substance, its metabolite(s), or marker(s) in the athlete's sample (usually urine) at any concentration, or the attempt to or the proof of using a forbidden method. The professional sports and National Collegiate Athletic Associations in the United States have their own prohibited lists, testing programs, and rules.

These sanctions restricted to the sport environment can have major economic, sportive, financial, or personal consequences and escape most of the time to the usual police and ordinary justice channels. One exception is doping agents' black market offenses, which are assimilated to trafficking of drugs of abuse. Some countries, however, have added to their own legislation specific laws that can also chase doping offenses directly.

Context of Adjudication of Anti-Doping Rule Violations in Sport

The WADA Anti-Doping Program was developed in 2000 through an international consensus process involving athletes,

sport leaders, and governments. More than 570 global sport organizations have now incorporated the WADA Code and its rules. The 158 governments (including the United States) who ratified the United Nations Education, Science and Cultural Organization (UNESCO) Anti-Doping Convention have also agreed to support the Program in their laws. So the Program truly represents an international consensus on how anti-doping rule violations should be addressed.

The burden of proof in anti-doping cases is not the criminal standard of beyond reasonable doubt, but rather the 'comfortable satisfaction' standard used for violation of professional standards by many medical, legal, and scientific organizations. Athletes agree to abide by the anti-doping rules as part of the rules of their sport and as a precondition of their participation in the competition.

Anti-doping analyses are generally conducted in two steps. First, a screening is performed. In the case of a positive result, a selective confirmation is carried out. Results should be released rapidly. Therefore, high-throughput techniques are used to screen in a single method a large set of compounds with different physicochemical properties while avoiding false negatives and reducing false positive results ($\leq 10\%$). Advanced automated analytical methods are especially useful during important sport events, when reporting results are required within 24–48 h.

The List of Prohibited Compounds and Methods to be Screened

The WADA has released six documents, three of which play a role in analytical method development:

1. The World Anti-Doping Code
2. The list of prohibited substances and methods
3. The International Standard for Laboratories

Forbidden compounds are placed on the list if they meet two of the following criteria:

1. The substance alone, or in combination with other substances, has the potential to enhance sport performance.
2. The substance represents an actual or potential health risk.
3. The substance violates the spirit of sport.

In addition, substances or methods that have the potential to mask the use of other prohibited substances are included. Currently, 209 substances are included in the list within several classes that include prohibitions effective at all times or in competition only. Examples of stimulants, narcotic analgesics, anabolic agents, diuretics, and peptide hormones are given for each class. The list's wordings include "... other substances with a similar chemical structure or similar biological effects." Therefore, one cannot claim to be not guilty because the detected drug that was used is not listed specifically by name.

Only nine prohibited molecules (parent drugs and/or their metabolites) have a cutoff concentration in urine. For the others, any detectable amount will constitute an 'adverse analytical finding,' at least down to the specified minimum required performance level (MRPL) fixed for the laboratory by WADA. For example, MRPL is ranging from milligram per liter (mg l^{-1}) for stimulants down to the low microgram per liter ($\mu\text{g l}^{-1}$) level for anabolic steroids.

Accredited laboratories have to screen for substances with various polarities and volatilities, from simple stimulants to complex peptides. The choice of technology is determined primarily by chemical characteristics (e.g., solubility in water or organic solvents, volatility, thermic stability, and polarity). It is achieved routinely by more than one procedure or instrumental method. A way to improve cost effectiveness of these analytical procedures is to maximize the number of analytes that can be determined in a single procedure (e.g., to use multicomponent techniques).

Biological Sample Identity and Integrity

In doping controlled urine, it is important to collect an authentic urine sample from the correct person, get it properly sealed, and document it for shipment to the laboratory. Targeted athletes are properly identified before providing a urine specimen. A minimum of 70 ml is required collected in a cup under direct supervision (to avoid urine substitution or adulteration) by an official of the same gender. A chain of custody paperwork documents follow the samples until they are finally discarded.

Blood is collected more frequently within the newly developed drug-testing programs of specific international sport federations. The procedure for taking around 10 ml of venous blood is carefully described in one of the WADA technical documents and follows in a more precise standardized way what is applied daily in clinics.

Specific Procedures in Dedicated Laboratories

As doping accusations can have major consequences, the whole analytical process is based on forensic guidelines, for example, strictly controlled, validated, secured, and verified procedures. Hence, accredited laboratories only are allowed to conduct anti-doping analyses.

In practice, each sample entering the laboratory is first classified into in- or out-of-competition sampling, but for ease, the same screening procedures are applied to all of them. The analytical procedures for the small (e.g., stimulants) and medium-sized molecules (e.g., derivatized steroids or glucocorticoids) are high-resolution gas chromatography (GC) with nitrogen-specific detection or high-pressure liquid chromatography (HPLC) with diode array detection, GC-mass spectrometry (GC-MS), and liquid chromatography-mass spectrometry (LC-MS) on the full scan mode or selected ion-monitoring mode. For larger molecules like the peptide hormones, immunoassays and isoelectrophoretic separation are preferred.

Statistics from WADA indicate that up to 280 000 samples have been analyzed around the world in 2009, out of which

Table 1 Distribution of the 3091 adverse analytical findings and 2519 atypical findings reported by the WADA-accredited Laboratories in 2009

Anabolic agents	64.8%
Cannabinoids	7.8%
Stimulants	6.4%
Beta-2 agonists	6.0%
Diuretics and other masking agents	5.4%
Glucocorticosteroids	5.2%
Hormones and related substances	2.0%
Hormones antagonists and modulators	1.0%
Beta-blockers	0.7%
Narcotics	0.5%
Chemical and physical manipulations	0.1%
Alcohol	0.1%
Enhancement of oxygen transfer	0.0%

1.1% have been declared as adverse analytical findings. Around 60% of these are anabolic steroids related to testosterone (Table 1).

In general, such a strictly controlled procedure for doping screening in sport is complex and includes the following key elements.

Chain of Custody

As far as the chain of custody is concerned, it starts well before the samples enter the laboratory after proper collection and tamper-proof transportation of the samples. Excessive temperature should be avoided for urines. It is known that a blood sample's composition changes rapidly over time and less stable doping parameters should be measured within a few hours after collection. Transportation at room temperature, or better around 4 °C, is preferred. This makes the handling of blood rather complex and expensive. In the laboratory, all processes including aliquots and extracts are recorded for the chain of custody requirements. This ensures the correct interpretation and reporting of the results and the appropriate disposal of the samples.

Validated Analytical Methodology

Analytical methods are implemented only if they have been correctly validated. The general procedure for method validation is defined in the International Organization for Standardization (ISO)/IEC 17025 companion documents. The accumulation of a vast body of analytical data is most often necessary to cover both intra- and interlaboratory variations. WADA is the ultimate body that allows the use of a newly developed procedure as was demonstrated for the introduction of the urine detection of erythropoietin (EPO) in 2002 or the biological passport (BP) in 2008.

Practical Analytical Approach

Only WADA-accredited laboratories are allowed to analyze official doping control samples in sport. The ISO/IEC 17025 requirements accreditation is the prerequisite condition to WADA accreditation. Mandatory requirements include among

others quality assurance program, standard operating procedures for each assay, instrumental operation and maintenance, personal qualifications, restricted access to the laboratory's surfaces, computers, and electronic records, internal audit trails, and traceability of results obtained from reference standards or excretion studies.

To comply with forensic quality standards mandated by the WADA Code, several objectives must also be met during the development of a specific doping test. An important validation step is to demonstrate robustness, that is, small changes in the proposed procedure or the use of another instrument have no impact on the final interpretation of the test results. Thus, laboratories have agreed between them the common analytical procedures and interpretation criteria for the confirmation of identity of the compounds of interest.

The general strategy for handling and analyzing doping samples within the laboratory is schematized in [Figure 1](#).

After registering each sample, the volume and the properties of the urine are recorded. The A-sample is then opened and the pH and density are measured together. Divided by groups of substances, the full screening can be covered by 8–12 separate analytical procedures (see [Table 2](#)) depending on the type of control (e.g., in- or out-of-competition).

For reasons of efficacy (highest sensitivity with best specificity), the most advanced analytical approaches are incorporated into doping controls. Today, mass spectrometry (MS), and particularly GC-MS, is so far considered the less likely technique to be challenged in court. Recently, liquid chromatography tandem mass spectrometry (LC-MS/MS) has been added to the extension of the panel of compounds already detected by GC-MS, including large, polar, and/or thermolabile substances. Over the last 5 years, the development of fast-switching MS/MS devices and smaller-diameter HPLC columns allows even more compounds to be screened from 2 ml of urine within less than 20 min of total analytical time.

Results are needed as soon as possible when the public is watching and when athletes compete more than once, because

if they have used drugs, they should be removed from the competition. Typically, the time elapsed between receiving the samples at the laboratory and reporting results is 10 days, but it can be as short as 24 h for negative results during major international sport events. Confirmation will take a longer time.

For blood, most drugs and some peptides are identified by GC-MS or LC-MS and biological parameters are measured through the laboratory medicine-automated procedures. Standardization of the values is gathered by running repetitively the corresponding stabilized standards just before and after the samples.

The Specific Analytical Techniques Involved in Doping Controls

Sample preparation

In doping controls, minimum volumes of urine (70 ml total) and blood (3–10 ml total) samples are available for the detection of all listed drugs including their metabolites.

The use of urine is still considered as best sample for doping controls, in part due to the relative ease of collection and because of the higher levels found in urine over blood.

The analytical criteria for reporting adverse analytical findings in screening are the following:

- At a minimum, the analysis should consist of two steps, namely, screening the A-sample and performing an A-sample confirmation.
- The order recommended for injection into the analytical instrument for confirmation analysis is (1) reagent blank, if pertinent; (2) negative control urine; (3) sample being confirmed; (4) negative control urine; and (5) positive control urine.

When an A-sample analysis confirms the presence of a banned substance, the laboratory reports it to the anti-doping

Figure 1 Place of the screening in the whole analytical process for doping controls. Before reporting an adverse finding, positives samples are always confirmed. For safety reasons, B-sample analysis – also called second confirmation or counteranalysis – is performed on the athlete's and/or sport authorities' request almost always in the same laboratory as the A-sample.

Table 2 Screening procedures in urine for the classes of prohibited substances and methods according the WADA 2011 list

<i>Prohibited substances/techniques</i>	<i>Immunoassay</i>	<i>GC</i>	<i>GC-MS</i>	<i>LC-MS or LC-MS/MS</i>	<i>Isoelectro focusing</i>	<i>Others</i>
AAS			X	X		
Beta-2-agonists			X			
Diuretics and other masking agents				X		
Hormones	hCG, LH, hGH				EPO	
Antiestrogens			X			
Stimulants		X	X			
Narcotics		X	X			
Glucocorticosteroids				X		
Cannabinoids	X		X			
Alcohol		X				
Beta-blockers			X	X		
Chemical and physical manipulations						Various simple tests
Enhancement of oxygen transfer			HES, RSR-13		HBOCs	HES dextran by biochemical analyzer
Gene doping						No urine test

AAS, anabolic androgenic steroids; HBOCs, hemoglobin-based oxygen carrier; hCG, chorionic gonadotrophin; HES, hydroxyethyl starch; hGH, human growth hormone; LH, luteinizing hormone; RSR-13, Efaproxiral, a pharmaceutical hemoglobin modifier.

organization. The athlete – known only by the anti-doping authority – is notified by that organization and has the right to ask for a B-sample confirmation. He can witness the analysis himself or send a representative of his choice. After completion and conclusion, which may take up to 3 days, the laboratory reports the B-sample confirmation results. What remains from the positive samples is securely frozen for the length of time that meets regulatory and/or contractual requirements. Negative samples can be usually disposed of without delay. For critical samples (e.g., those collected during Olympic Games), the authorities may ask to preserve all the intact B-sample vials. WADA code allows retrospective analyses on these urines up to 8 years later. This is to take advantage of the development of new methods of detection during this time period.

Main Analytical Techniques

GC-MS detection

Automated GC-MS instrumentation is best suited to run many samples in a short period of time and to eliminate efficiently the many negatives. Modern MS instruments allow both automatic injection and treatment of the results. In general, total ion or selected ion current traces are generally very complex even at restricted time windows and targeted substances might be hidden behind the biological matrix background noise. A qualified laboratory technician will read the printed reports, with a second person, usually a senior scientist, verifying the findings. Because of so many true negative results (>95%) even at low $\mu\text{g l}^{-1}$ concentration levels, the doping analyst should get best compromise between selectivity of the extraction and high recovery yield, speed, and low cost. Liquid-liquid partitioning or solid phase extraction, either manual or automated, is most commonly used. Immunoaffinity chromatography and HPLC fraction collection have been recently introduced for improved

reduction of the biological background to enable higher signal to noise ratios and improved detection limits.

GC-MS remains the technology of choice for the detection of anabolic steroids until the appearance in 2006 of tetrahydrogestrinone (THG) as a designer steroid, which was almost undetectable by the screening methods used at that time. The discovery of THG has led to the introduction of LC-MS/MS as an additional screening technology. As a result, GC-MS and LC-MS are now used as complementary techniques in doping control.

LC-MS detection

The high polarity of the conjugates eliminated in urine limits the use of GC-MS to hydrolyzed samples only. Such measurements offer targeted molecules with modified structure for identification and rather imprecise quantitative measurements of each individual moiety. One of the major advantages of liquid-based chromatography with MS is that the direct detection of thermolabile and polar compounds or metabolites involved in sport doping is possible. Now direct injection of diluted biological samples is even possible by ultra pressure liquid chromatography-tandem mass spectrometry provided sufficient resolving chromatographic power is obtained.

Developments in accurate-mass detection

Conceptually achieved by the use of GC or LC in combination with full scan, accurate-mass time of flight-mass spectrometry (TOF-MS) or orbitrap MS, this new approach has gained popularity. The advantage of a full scan MS is its ability to analyze a sample for a theoretically unlimited number of compounds. Furthermore, data can be acquired and reprocessed without prior knowledge about the presence of specific molecule (e.g., no analyte-specific information is required before injecting a sample and the presence of newly identified compounds can be confirmed in previously analyzed samples simply by

reprocessing the data). As the number of forbidden doping agents is constantly expanding, the capability to identify compounds without reference standards is a clear advantage.

A general screening method for doping agents in human urine based on solid-phase extraction and LC-TOF-MS was developed and validated in 2007.

Discrimination Between Endogenous and Exogenous Doping Agents

Pharmaceutical testosterone and natural testosterone mass spectra are identical when measured with ordinary MS detectors. In recent years, gas chromatography-carbon on-line combustion isotope ratio mass spectrometry (GC-C-IRMS) has been developed to make it possible to discriminate exogenous testosterone from endogenous testosterone by measuring $^{13}\text{C}/^{12}\text{C}$ ratio in these steroids and their metabolites. Since the 1998 Olympic Winter Games in Nagano, GC-C-IRMS has been an accepted method in doping controls. However, a relatively large volume of urine (~25 ml) is necessary and a time-consuming cleanup procedure is needed to obtain highly purified steroid fractions.

Criteria for Identification

Identification of a small molecule based on its mass spectrum is usually obtained by comparing spectra of the unknown sample by running on the same day the corresponding reference compound or standard through the same analytical procedure and instrumentation. In this way, the laboratory minimizes instrumental variations leading to slightly different MS to meet the required criteria of WADA for identification.

The Availability of Reference Doping Substances

Many doping substances are available at the requested purity for reference purpose through chemical manufacturers. However, most of the metabolites do not have readily available commercial sources and consequently no purity data are available. Consequently, all the laboratories prepare their own certified urines from controlled excretion studies. After the relevant permission from the medical ethics committee is granted, a small and unique dose of the doping agent is given to one volunteer. This healthy individual delivers several urine samples that allow the laboratory to trace and identify most relevant metabolites. After being analyzed, the remaining samples are mixed together. Aliquots are kept at a low temperature until used as reference samples.

Analytical Approach for Large Molecules and Peptide Detection

These screenings are basically performed by immunoassays directly on the urine or blood, or after specific manipulation of the samples (e.g., after ultrafiltration and concentration, blotting transfer, and electrophoretic separation). In principle, formal confirmation can be obtained by using other immunological tests acting on a different epitope of the targeted molecule.

The Biological Passport

The idea of a biological follow-up for athletes was first mentioned in 2002. The BP is based on the measurements of several key biological parameters (mainly in blood), the variation of which provides evidence of the use of banned substances.

First, it is necessary to establish the normal hematological profile of each individual athlete. All these parameters (e.g., hematocrit, hemoglobin content, etc.) are measured by standardized protocols in order to compare the values. To cover the forensic requirements, a statistical model based on the Bayesian approach is applied where the range of the normal variation of each parameter is defined on the same individual. Seven independent measurements are necessary before any prediction on the normal minimum and maximum values can be made. If these individual limit values are exceeded, doping sanctions can be made because such abnormality demonstrates manipulation of the blood parameters. The BP will possibly allow the detection of any kind of blood manipulation. The first case of abnormal hematological profile demonstrated by the BP passed successfully the Court for Arbitration in Sport (CAS) scrutiny in early 2011.

Developments for the Future

The continuous implementation of new analytical techniques to target a wider range of chemicals improves the deterrent effect of the controls. HPLC with matrix-assisted laser desorption ionization time-of-flight MS for determining protein molecular mass shows interesting promises for new applications, but requires additional development and validation before routine use in anti-doping laboratories. Against the recent outcome of new biotechnologies and new protocols for doping (e.g., EPO through micro doses, manipulation through blood autologous transfusions, use of growth factors, and cellular therapies), the present system should also find new strategies.

Targeted controls on suspicious athletes might also offer better yield for adverse analytical findings. The recent introduction of BP opens new possibilities. With high-quality intelligence information available, a more aggressive approach to catching cheating athletes can be developed. However, the high costs of such a program might restrict its implementation.

Glossary

Abuse Excessive or improper use of drugs or other substances.

Acute Sudden or short-term.

Anesthetic A substance producing either local or general loss of sensation.

Arrhythmia Any variation from the normal rhythm of the heartbeat.

Biological specimens Samples of tissues (including blood, hair), secretions (breast milk, saliva, sweat), excretion products (bile, exhaled air, urine), and other material such as stomach contents or vomit derived from a patient.

First-pass metabolism The portion of an oral dose metabolized in the intestine, gut wall, or liver before reaching the systemic circulation.

Headspace The space above a solid or liquid in a container.

Ingestion Taking of substances into the body by mouth.

Intoxication Excitement or elation induced by alcohol or other drugs (also referred to as inebriation).

Limit of detection The smallest amount of a substance that can be revealed by a test carried out in a prescribed manner.

Methemoglobinemia The presence of abnormal amounts of oxidized hemoglobin in blood.

Pharmacokinetics The study of the rates of the processes involved in the absorption, distribution, metabolism, and elimination of drugs and other agents.

Plasma half-life The time taken for the plasma concentration of a substance to decrease by half.

Scene residue Material found at the scene of a crime, suicide, or other event.

Acute poisoning with volatile substances is encountered most commonly following the deliberate inhalation of vapor in order to become intoxicated ('glue sniffing,' 'huffing,' 'dusting,' 'bagging,' inhalant abuse, solvent abuse, volatile substance abuse (VSA), volatile substance misuse). Solvents from adhesives and in paint thinners such as toluene, hydrocarbons such as those found in cigarette lighter refills and aerosol propellants (often purified liquefied petroleum gas (LPG)), polyhalogenated hydrocarbons such as those used as refrigerants and in 'chemical dusters,' and anesthetic gases such as nitrous oxide are among the compounds/products that may be abused in this way (Tables 1 and 2).

Since the mid-1970s, in many countries, there has been phased withdrawal of volatile organochlorine and organobromine compounds, such as hydrochlorofluorocarbon (HCFC) refrigerants and aerosol propellants, thought to be potent ozone depleters. This has led to increased use of polyfluorinated compounds such as difluoromethane (HFC 32), pentafluoroethane (HFC 125), 1,1,1,2-tetrafluoroethane (HFC 134a), and 1,1,1-trifluoroethane (HFC 143a), and to a lesser extent perfluoropropane (PFC 218). In addition, 1,1-dichloro-1-fluoroethane (HCFC 141b) has been introduced as a degreasing and foaming agent (Table 1). However, the misuse potential of the newer compounds/products is just as high as those they have replaced.

LPG arises from the cracking of oil to make petrol (petroleum spirit, gasoline, benzine) and also in the gases trapped above oil fields. There are at least two grades of LPG available to volatile substance abusers, namely (i) unpurified gas intended for direct use as a fuel and (ii) purified gas intended primarily for cigarette lighter refills and as a propellant in aerosols and related products. The composition of LPG can vary depending on the source although its major components are usually butane, isobutane, and propane. Some unpurified LPGs can contain up to 40% (v/v) unsaturates (butenes and

propene). Petrol itself is often abused, especially in less-developed communities where access to other abusable volatiles is limited.

Isobutyl, isopentyl ('amyl'), and isopropyl nitrites and related compounds ('poppers') may also be inhaled in order to experience their vasodilator properties, sometimes by men who have sex with men. Inhalation of the vapor of a range of other substances ranging from mothballs (naphthalene or 1,4-dichlorobenzene) to chlorine has also been reported, but such pastimes are uncommon. On the other hand, diesel fuel, aviation fuel (kerosene, Avgas), white spirit, turpentine (or substitute), and paraffin are not sufficiently volatile to be abused by inhalation. Similarly, nail varnish or varnish remover (acetone and esters) and nitroethane (used as an artificial fingernail remover) do not have properly documented examples of abuse, probably because they are either too water-soluble or too involatile to be intoxicants. By the same token, acetone has never been used as an anesthetic.

In addition to those who deliberately inhale volatiles, people who ingest, or even more rarely inject, solvents or solvent-containing products, either accidentally or deliberately, and the victims of clinical, industrial, and domestic accidents may be poisoned by the compounds under consideration. Finally, chloroform (trichloromethane), diethyl ether, and other volatiles are still used occasionally in the course of crimes such as rape and murder, while a further volatile compound, chlorobutanol (1,1,1-trichloro-2-methyl-2-propanol), sometimes employed as a sedative and a preservative, has been used in doping racing grayhounds.

VSA can produce dose-related central nervous system effects similar to those of ethanol. Small doses can lead rapidly to euphoria and other behavioral disturbances, and may also induce more profound effects such as delusions and hallucinations. Heightened sexual (self-) gratification may also be a feature, sometimes in association with partial asphyxia. Once

exposure ceases, rapid recovery normally ensues – rapid recovery after exposure may be a factor in the continuing popularity of VSA among children of high school age (13–18 year-olds) in some countries. On the other hand, psychological dependence is common in chronic users. VSA has now been reported from most parts of the world, mainly among adolescents, individuals living in remote communities, and those with occupational access to abusable volatiles.

Indirect toxicity from VSA may also occur. For example, lead poisoning was common when lead-containing petrol was abused, methanol toxicity has been reported in Native American Indian communities secondary to abuse of carburetor cleaning solution, and there has been a report of deposition of titanium-containing granules in lung after presumed inhalation of toluene-based spray paint. There is also the risk of explosion and fire when flammable volatiles such as LPG are abused in confined spaces and a source of ignition is at hand. Hydrofluoric acid burns have been observed following ignition of 1,2-difluoroethane from compressed air cleaners.

The major risk from VSA is that of sudden death. There were at least 2343 (2000 male) VSA-related deaths in the United Kingdom during 1971–2008 (Figure 1), some 5% of which are thought to have been suicides. There have been many reports of VSA-related sudden deaths worldwide, again predominantly in adolescent males, although epidemiological studies indicate that equal numbers of males and females experiment with VSA. Overall, some 49% of UK VSA-related sudden deaths occurred in adolescents aged 14–18 years, with a further 5% in children aged 7–14 years, although there has been a trend toward an increase in the age at death in recent years. Some deaths were attributed to 'indirect' causes such as inhalation of vomit (8.9% of UK VSA-related deaths, 1999–2008), asphyxia associated with the use of a plastic bag to contain the vapor being inhaled (11.9%), and trauma (5.2%). However, most UK deaths in this period (70.9%) were attributed to direct toxicity ('sudden

Table 2 Some products that may be abused by inhalation

<i>Product</i>	<i>Major volatile components</i>
Adhesives	
Balsa wood cement	Ethyl acetate
Contact adhesives	Butanone, hexane, toluene, and esters
Cycle tire repair cement	Toluene and xylenes
Polyvinylchloride (PVC) cement	Acetone, butanone, cyclohexanone, and trichloroethylene
Woodworking adhesives	Xylenes
Aerosols	
Air freshener	LPG, DME, and/or fluorocarbons ^a
Deodorants, antiperspirants	LPG, DME, and/or fluorocarbons ^a
Fly spray	LPG, DME, and/or fluorocarbons ^a
Hair lacquer	LPG, DME, and/or fluorocarbons ^a
Paint	LPG, DME, and/or fluorocarbons ^a and esters
Anesthetics/analgesics	
Inhalational	Nitrous oxide, cyclopropane, diethyl ether, halothane, enflurane, desflurane, isoflurane, methoxyflurane, sevoflurane, and xenon
Topical	Ethyl chloride and fluorocarbons ^a
Balloon gas	Helium, nitrous oxide
Carburettor cleaner, commercial dry cleaning and degreasing agents, surgical plaster/chewing gum remover	DME, dichloromethane, HCFC 113, HCFC 141b, methanol, 1,1,1-trichloroethane, tetrachloroethylene, toluene, and trichloroethylene (now very rarely carbon tetrachloride, 1,2-dichloropropane)
Cooking oil sprays	Diethyl ether
Domestic spot removers and dry cleaners	Dichloromethane, 1,1,1-trichloroethane, tetrachloroethylene, and trichloroethylene
Dust removers ('air brushes')	DME and fluorocarbons ^a
Firefighting agent (older products)	(BCF, HCFC 11, HCFC 12), HFC 125, HFC 227ea, HFC 236fa, HFC 23, HCFC 123
Fuel gases	
Cigarette lighter refills	LPG
'Butane'	LPG
'Propane'	Propane and butanes
Starting fluid	Diethyl ether, DME, heptane, and LPG
Injected oxidant (racing fuel supercharge, blowtorches)	Nitrous oxide
Paints (including spray paints)/paint thinners	Acetone, butanone, esters, hexane, methanol, toluene, trichloroethylene, and xylenes
Paint stripper	Dichloromethane, methanol, and toluene
Refrigerant (or coolant) gas	DME, HFC 125, HFC 134a, HFC 143a, HFC 32, HCFC 124
Room odorizer	Isobutyl nitrite
Typewriter correction fluids/thinners (older products)	(1,1,1-Trichloroethane)
Varnishes/lacquers	Xylenes
Whipped cream dispensers	Nitrous oxide

See **Table 1** for full chemical names of some compounds.

^aMainly HFC 134a and/or HFC 152a, HFC 227ea.

sniffing death'), predominantly in relation to the abuse of fuel gases, aerosol propellants, and halogenated solvents as compared to deaths due to abuse of solvents from adhesives. In 2008, some 83% of UK VSA-related deaths were attributed to the abuse of LPG or other fuel gases (**Figure 2**).

The implementation of a European Union Directive (2005/95/EC) that restricts the use of toluene in household and other products (December 2006), together with the introduction (January 2007) of the first phase of the provisions of the volatile organic compounds (VOCs) in Paints, Varnishes and Vehicle Refinishing Products Regulations 2005 has served to restrict the availability of some easily abusable products. Legislation in England and Wales to restrict the sale of cigarette lighter refills to those under the age of 16 has also been enacted, and these measures may have contributed to the decline in UK VSA-related deaths in recent years. The use of 'poppers' (alkyl nitrites) is also restricted in the United Kingdom and in many countries on product safety grounds as some of these compounds are classed as carcinogens.

These factors may also have helped reduce crime associated with VSA in the United Kingdom. An audit of press reports of VSA-related crime/antisocial behavior in 1997–2007 (589 individuals) showed that, in line with the trend seen in UK VSA-related deaths, not only were 89% of offenders male, but also that there was a decrease in reports of VSA-related offenses with time (84 in 1997, 20 in 2007). The agents reported (17 individuals, 2 agents) were 'glue' 225, LPG/'butane'/aerosol propellants 176, 'solvents' 158, and petrol (gasoline) 27. The offenses cited (most serious crime) included homicide (35), rape or other sexual assault (34), and arson (25). Many of the offenders were recidivists, and 66% were aged 20 years or more at the time of the first offense.

VSA is often a solitary pastime and the intent to achieve intoxication may be clear, although when someone has died, the circumstances under which death occurred may be disguised. However, VSA is sometimes a shared habit, on occasions accompanied by sexual or attempted sexual activity. If one or indeed both partners die during or immediately after

Figure 1 UK VSA-related sudden deaths, 1971–2008 ($N = 2343$). Data from Ghodse H, Ahmed K, Corkery J, Naidoo V, and Schifano F (2010) *Trends in UK Deaths Associated with Abuse of Volatile Substances, 1971–2008*. Figure 2 UK VSA-related deaths, 1982–2008 ($N = 2244$) by type of product abused. Data from Ghodse H, Ahmed K, Corkery J, Naidoo V, and Schifano F (2010) *Trends in UK Deaths Associated with Abuse of Volatile Substances, 1971–2008*. London: International Centre for Drug Policy, St George's, University of London. <http://www.solveitonline.co.uk/images/vsa-annual-report-23-2010-final-version.pdf> (accessed 24 August 2011).

the episode of VSA, then it can be very difficult to ascertain intent, the options being accident, suicide, manslaughter (culpable homicide), and even murder. There have long been suicides facilitated by use of volatile compounds, especially among anesthetists and others with access to not only the agent, but also the necessary equipment with which to self-administer the agent. Often the circumstances of the death help guide the diagnosis, although even here it is sometimes difficult to ascertain intent. A more recent trend reported from several countries has been the use of asphyxiant gases such as helium or nitrogen to facilitate suicide, a trend made possible by the widespread availability of compressed gas in cylinders. Deaths attributed to deliberate helium inhalation in the United Kingdom increased from 2 in 2001 to 25 in 2008, for example. Clearly, such cases present special problems to the analyst charged with helping investigate the death.

Diagnosis of VSA

Clinically, VSA should be considered in children and adolescents with 'drunken' behavior, unexplained listlessness, anorexia, and moodiness. The hair, breath, and clothing may smell of solvent, and empty adhesive tubes or other containers, potato crisp bags, cigarette lighter refills, or aerosol spray cans are often found in unusual places such as secreted in bed clothes. The smell of solvent in the breath is related to the dose and duration of exposure and may last for many hours. The so-called glue-sniffer's rash (perioral eczema) is probably caused by repeated contact with glue in a plastic or other bag held to the face. Adolescents who indulge in VSA often have a personal history of trauma, suicidality, psychiatric distress, and antisocial behavior. Although primarily a phenomenon of adolescence, it must be remembered that adults, especially

those with occupational access to abusable volatiles, also indulge in VSA. In the late 1970s, for example, it was estimated that some 1–1.6% of US dentists were abusing nitrous oxide.

Although chronic abuse of some volatiles may give rise to long-term sequelae, for example, abuse of nitrous oxide may cause myeloneuropathy secondary to vitamin B₁₂ deficiency, the underlying mechanism of toxicity is not always clearly defined. If substances such as LPG are sprayed directly into the throat, this may cause rapid cooling of the vagus nerve, and may also cause laryngeal edema, laryngospasm, and even frostbite. Stimulation of the vagus nerve can lead to bradycardia, myocardial ischemia, coronary vasospasm, and cardiac arrest. The contents of lighter refills may be inhaled more easily by simply grasping the nozzle between the teeth and pressing while keeping the cylinder upright. Aerosols are either sprayed into a plastic bag to allow the aerosol to settle before inhaling the gas, or simply bubbled through water to remove the product before inhaling the propellant. In either case, displacement of oxygen in the inspired air may lead to asphyxia, but if exposure is continued, butane, especially, may accumulate in the body.

It is thought that butane and most halogenated hydrocarbons sensitize the heart to adrenaline, that is, there is an excessive response to release of adrenaline particularly in the context of a 'fight or flight' situation (sudden shock), or pronounced sexual stimulation, especially if accompanied by physical restriction on the ability to inspire oxygen (sexual asphyxia). In turn, this may give rise to cardiac arrhythmia, ventricular fibrillation, and eventually cardiac arrest. Although it is rare for someone who has suffered a cardiac arrest after inhaling volatiles to be resuscitated, it has been suggested that emergency staff should administer amiodarone and use physical measures to normalize heart function rather than giving adrenaline in such a situation.

Laboratory Analysis

The analytical toxicology laboratory may be asked to perform analyses for solvents and other volatile compounds in biological samples and related specimens to (i) confirm a suspicion of chronic VSA in the face of denial from the patient and/or a caretaker; (ii) aid the investigation of deaths where poisoning by volatile compounds is a possibility, including deaths associated with anesthesia; (iii) aid investigation of rape or other assault, or other offense such as driving a motor vehicle or operating machinery, which may have been committed while the victim and/or the accused may have been under the influence of volatile substances; (iv) aid investigation of incidents such as rape or other assault in which volatile substances may have been forcibly administered to the victim; (v) help investigate fire or explosion where VSA might have been a contributory factor; and (vi) assess occupational or environmental exposure to anesthetic or solvent vapor. However, other techniques such as ambient air monitoring or, in a few instances, the measurement of urinary metabolite excretion may be more appropriate in this latter context.

The laboratory analysis of volatile substances presents particular problems. First, many of the compounds of interest occur commonly either in the environment or in laboratories, and this necessitates special precautions against contamination

and interference. Second, collection, storage, and transport of biological samples must be controlled as far as practicable in order to minimize loss of analyte – quantitative work is futile if very volatile compounds such as propane are encountered unless special precautions are taken to prevent the loss of analyte from the sample prior to the analysis. Third, many compounds of interest are excreted unchanged via the lungs (Table 3) and thus whole blood (and/or other tissues in fatalities), and not urine, is usually the sample of choice. Finally, the interpretation of results can be difficult, especially if legitimate exposure to solvent vapor is a possibility.

Analytical Methods

The analysis of biological samples for solvents and other volatiles has similarities to the analysis of ethanol, methanol, and 2-propanol. Headspace gas chromatography (HS-GC) with flame ionization detection (FID) and/or electron capture detection (ECD) or mass spectrometric (MS) detection is widely used in the analysis of volatiles in blood and other biological specimens. Headspace solid-phase micro-extraction has also been employed. Nitrous oxide and most halogenated compounds respond to the ECD. Use of nitrogen as a carrier gas has facilitated detection of helium in postmortem specimens.

Direct MS of expired air can detect many compounds several days postexposure. However, the use of this technique is somewhat limited by the need to take breath directly from the patient. Inertial spray MS allows introduction of biological fluids directly into the MS without prior chromatographic analysis and has been used in the analysis of halothane in blood during anesthesia. Vapor-phase infrared (IR) spectrophotometry may be useful in the analysis of abused products or ambient atmospheres. High-performance liquid chromatography may be useful in the analysis of certain solvent metabolites such as hippuric acid (Table 4).

If the analyte is very volatile (e.g., propane, butane) and a quantitative analysis is required, a blood sample should be collected directly into the headspace vial in which the analysis will be carried out. Other, less volatile compounds are relatively stable in blood and other tissues if simple precautions are taken. In the case of blood, the container used for the sample should be glass, preferably with a cap lined with metal foil; greater losses may occur if plastic containers are used. The tube should be as full as possible and should only be opened when required for analysis, and then only when cold (4 °C). If the sample volume is limited, it is advisable to select the container to match the volume of blood so that there is minimal headspace. An anticoagulant (sodium ethylenediamine tetra-acetate (EDTA) or lithium heparin) should be used. Specimen storage between –5 and 4 °C is recommended and 1% (w/v) sodium fluoride should be added to minimize esterase and other enzymic activity.

Tissues (~10 g each of brain, lung, liver, kidney, and subcutaneous fat) should also be obtained if a necropsy is performed in addition to standard toxicological specimens (femoral blood, urine, stomach contents, vitreous humor). Tissues should be stored before analysis in the same way as blood. No preservative should be added. Any products thought to have been abused or otherwise implicated in the incident (and stomach contents if ingestion is suspected)

Table 4 Summary of the metabolism of some solvents and other volatile substances

<i>Compound</i>	<i>Principal metabolites (% absorbed dose)</i>	<i>Notes</i>
Acetone	2-Propanol (minor) and intermediary metabolites (largely excreted unchanged at higher concentrations)	Endogenous compound produced in large amounts in diabetic or fasting ketoacidosis; also the major metabolite of 2-propanol in man
Acetonitrile	Inorganic cyanide (at least 12%) thence to thiocyanate	Cyanide/thiocyanate may accumulate during chronic exposure
Benzene	Phenol (51–87%), catechol (6%), hydroquinone (2%), <i>trans, trans</i> -muconic acid	Excreted in urine as sulfate and glucuronide conjugates. Urinary phenol excretion has been used to indicate exposure but is variable and subject to interference
Bromomethane	Inorganic bromide	Serum bromide has been used to monitor exposure, although the concentrations associated with toxicity are much lower than when bromide itself is given orally
Butanone	3-Hydroxybutanone (0.1%)	3-Hydroxybutanone excreted in urine. Most of an absorbed dose of butanone excreted unchanged in exhaled air
Carbon disulfide	2-Mercapto-2-thiazolin-5-one, 2-thiothiazolidine-4-carboxylic acid (TCCA), thiourea, inorganic sulfate, and others	2-Mercapto-2-thiazolin-5-one glycine conjugate and TCCA glutathione conjugate of carbon disulfide. Urinary TCCA excretion is a reliable indicator of exposure
Carbon tetrachloride	Chloroform, carbon dioxide, hexachloroethane, and others	Trichloromethyl free radical (reactive intermediate) is probably responsible for hepatorenal toxicity
Chloroform	Carbon dioxide (up to 50%), diglutathionyl dithiocarbonate	Phosgene (reactive intermediate) depletes glutathione and is probably responsible for hepatorenal toxicity
Cyclohexanone	Cyclohexanol, <i>trans</i> -1,2-cyclohexanediol, <i>trans</i> -1,4-cyclohexanediol	Metabolites excreted mainly as glucuronides in adults
Desflurane	Trifluoroacetic acid (<0.02%), inorganic fluoride	–
Dichloromethane	Carbon monoxide (approximately 35%)	Carboxyhemoglobin half-life 13 h (carboxyhemoglobin half-life 5 h after inhalation of CO). Blood carboxyhemoglobin measurement is a useful indicator of chronic exposure
Dimethylsulfoxide	Dimethylsulfide (3%), dimethylsulfone (18–22%)	After oral/dermal administration, dimethyl sulfide excreted in exhaled air and dimethylsulfone in urine
Dioxane	β -Hydroxyethoxyacetic acid (HEAA)	HEAA excreted in urine
Enflurane	Difluoromethoxydifluoroacetic acid (>2.5%), inorganic fluoride	–
Ethyl acetate	Ethanol, acetic acid	Rapid reaction catalyzed by plasma esterases
Ethylbenzene	Methylphenylcarbinol (5%), mandelic acid (64%), phenylglyoxylic acid (25%)	Methylphenylcarbinol excreted in urine as conjugate, others as free acids. Mandelic acid excretion has been used to monitor ethylbenzene exposure
Halothane	2-Chloro-1,1,1-trifluoroethane, 2-chloro-1,1-difluoroethylene, trifluoroacetic acid, inorganic bromide, and others	The formation of reactive metabolites may be important in the etiology of the hepatotoxicity ('halothane hepatitis') that may occur in patients re-exposed to halothane or similar compounds
Hexane	2-Hexanol, 2-hexanone, 2,5-hexanedione	2-Hexanol excreted in urine as glucuronide. 2,5-Hexanedione thought to cause neurotoxicity. Methyl butyl ketone also neurotoxic and also metabolized to 2,5-hexanedione
Isobutyl nitrite	2-Methyl-1-propanol (99%+), inorganic nitrite	Parent compound not normally detectable in blood. Blood methemoglobin can be used to monitor exposure
Isoflurane	Trifluoroacetic acid (<0.2%), inorganic chloride, inorganic fluoride	–
Isopentyl nitrite	3-Methyl-1-butanol (99%+), inorganic nitrite	Parent compound not normally detectable in blood. Blood methemoglobin can be used to monitor exposure
Isopropyl nitrite	2-Propanol, inorganic nitrite	Parent compound not normally detectable in blood. Blood methemoglobin can be used to monitor exposure
Methanol	Formaldehyde (up to 60%), formic acid	Urinary formic acid excretion has been advocated for monitoring methanol exposure
Methoxyflurane	Methoxydifluoroacetic acid, dichloroacetic acid, oxalic acid, inorganic fluoride	Abuse has been manifested as chronic fluoride poisoning (fluorosis)
2-Propanol	Acetone (80–90%) thence others	2-Propanol half-life approximately 2 h, acetone half-life approximately 22 h
Sevoflurane	1,1,1,3,3,3-Hexafluoropropanol (<3%), inorganic fluoride	1,1,1,3,3,3-Hexafluoropropanol excreted as glucuronide in urine
Styrene	Mandelic acid (85%) and phenylglyoxylic acid (10%); hippuric acid may be minor metabolite	Urinary mandelic acid excretion indicates exposure. Ethanol inhibits mandelic acid excretion
Tetrachloroethylene	Trichloroacetic acid (<3%)	Urinary trichloroacetic acid excretion serves only as qualitative index of exposure

(Continued)

Table 4 (Continued)

Compound	Principal metabolites (% absorbed dose)	Notes
Toluene	Benzoic acid (80%) and <i>o</i> -, <i>m</i> -, and <i>p</i> -cresol (1%)	Benzoic acid largely conjugated with glycine giving hippuric acid which is excreted in urine (half-life 2–3 h). Not ideal index of exposure since there are other (dietary) sources of benzoic acid
1,1,1-Trichloroethane	2,2,2-Trichloroethanol (2%) and trichloroacetic acid (0.5%)	Urinary metabolites serve as qualitative index of exposure only (compare tetrachloroethylene)
Trichloroethylene	2,2,2-Trichloroethanol (45%) and trichloroacetic acid (32%)	Trichloroethanol (glucuronide) and trichloroacetic acid excreted in urine (half-lives about 12 and 100 h, respectively). Trichloroacetic acid excretion can indicate exposure
Xylenes	Methylbenzoic acids (95%) and xylenols (2%)	Methylbenzoic acids conjugated with glycine and urinary methylhippuric acid excretion used as index of exposure – no dietary sources of methylbenzoates

should be packed, transported, and stored entirely separately from (other) biological specimens to avoid cross-contamination. Investigation of deaths occurring during or shortly after anesthesia should include the analysis of any residue of the anesthetic used in order to exclude an administration error.

The likelihood of detecting exposure to volatile substances in blood is influenced by the dose and duration of exposure, the time of sampling in relation to the time elapsed since exposure, and the precautions taken in the collection and storage of the specimen. In postmortem work, other factors may be important such as the time elapsed between death and sampling. In a suspected VSA- or anesthetic-related fatality, analysis of tissues (especially brain) may prove useful as high concentrations of volatile compounds may be present even if very little is detectable in blood. Detection of the volatile compounds in adipose tissue may, however, suggest chronic rather than acute exposure.

Gas Chromatography

Bonded-phase wide-bore capillary columns permit relatively large-volume septum injections and offer good efficiency, reproducibility, and reliability. A 60 m × 0.53 mm i.d. fused silica capillary coated with the dimethylpolysiloxane SPB-1 (5 μm film thickness) programmed from 40 to 200 °C offers many advantages over packed column systems. Improved resolution of very volatile compounds is obtained and, even with an initial temperature of 40 °C, the total analysis time can be reduced to 26 min, and good peak shapes can be obtained even for alcohols (Figure 3). Moreover, splitless septum injections of up to 300 μl headspace can be performed with no noticeable effect on column efficiency; hence, sensitivity is at least as good as that attainable with a packed column.

The use of a capillary column together with two different detectors confers a high degree of selectivity, particularly for low formula mass compounds where there are few alternative structures. However, GC–MS can be difficult when the fragments produced are less than *m/z* 40, particularly if the instrument is used for other purposes as well as solvent analyses. In particular, the available sensitivity and spectra of the low-molecular-weight alkanes renders them very difficult to confirm by GC–MS. GC combined with Fourier transform infrared (FTIR) spectrometry may have some advantages over GC–MS in the analysis of volatiles, but sensitivity is poor, particularly when compared with the ECD. In addition, interference,

Figure 3 Analysis of a whole blood sample obtained postmortem from a patient who had inhaled the contents of a cigarette lighter refill. Sample preparation: internal standard (IS) solution (ethylbenzene and 1,1,2-trichloroethane (~25 and 10 mg l⁻¹, respectively) in outdated blood-bank whole blood) (200 μl) incubated (65 °C, 15 min) with specimen (200 μl) in a sealed 10 ml glass septum vial. Chromatographic conditions: column: 60 m × 0.53 mm i.d. SPB-1 (5 μm film). Oven temperature: 40 °C (6 min), then to 80 °C at 5 °C min⁻¹, then to 200 °C at 10 °C min⁻¹. Injection: 300 μl headspace.

particularly from water and carbon dioxide in the case of biological specimens, can be troublesome.

‘Purge and trap’ and multiple headspace extraction offer ways of increasing sensitivity and, although not needed for most clinical and forensic applications, have been used either in conjunction with GC–FTIR or in occupational/environmental monitoring. Pulse heating has also been employed in the analysis of volatiles in biological specimens. Advantages of this latter technique include use of a small sample volume (0.5–5 μl), short extraction time, and lack of matrix effects.

Interpretation of Analytical Results

A diagnosis of VSA should be based on a combination of circumstantial, clinical, and analytical evidence rather than on any one factor alone. It is especially important to consider all circumstantial evidence in cases of possible VSA-related

sudden death as suicide or even homicide cannot be excluded simply on the basis of the toxicological examination. There has been one example in the United Kingdom of a serial murderer whose victims were thought initially to have died accidentally as a result of VSA.

Knowledge of the pharmacokinetics of volatile compounds is important in understanding the rate of onset, the intensity, and the duration of intoxication with these substances. The UK Workplace Exposure Limits (Table 3) provide information on the relative toxicities of different compounds after chronic exposure to relatively low concentrations of vapor. The solubility of a volatile compound in blood is an important influence on the rate of absorption, tissue distribution, and elimination of the compound. Due to the large surface area of the lungs, blood concentrations peak minutes after inhalational exposure, distributing rapidly into well-perfused tissues (i.e., brain, heart). If exposure continues, the inhalant will distribute into the poorly diffused tissues such as fat. After ingestion, hepatic metabolism may reduce systemic availability ('first-pass' metabolism), and diffusion into tissues often limits the amount of substance available to get to the brain. Moreover, there may be less displacement of oxygen from the lungs than if solvent vapor had been inhaled directly.

The partition coefficients of a number of compounds between air, blood, and various tissues have been measured *in vitro* using animal tissues, and some *in vivo* distribution data have been obtained from postmortem tissue measurements in man (Table 3). However, these latter data must be used with caution as there are many difficulties inherent in such measurements (sampling variations, analyte stability, external calibration, etc.). Similarly, published data on the elimination half-lives of volatile substances (Table 3) are not easily comparable, either because too few samples were taken, or the analytical methods used did not have sufficient sensitivity to measure the final half-life accurately. Plasma concentrations of some compounds may fall monoexponentially, while others may exhibit two (or more) separate rates of decline (half-lives) due to distribution to, and elimination from, poorly perfused tissues.

Exogenous compounds may be metabolized in a number of ways, a frequent result being the production of metabolites of greater polarity (water solubility) and thus lower volatility than the parent compound. The pharmacological activity and pharmacokinetics of any metabolite(s) often differ from those of the parent compound(s). However, many volatile substances, including not only inert gases such as helium and nitrogen, but also butane, dimethyl ether (DME), most fluorocarbon refrigerants/aerosol propellants/anesthetics, isobutane, nitrous oxide, propane, tetrachloroethylene, and 1,1,1-trichloroethane are largely eliminated unchanged in exhaled air. Others are partly eliminated in exhaled air and also metabolized in the liver and elsewhere (Table 4), the metabolites being eliminated in exhaled air or in urine, or incorporated into intermediary metabolism.

When interpreting the results of qualitative analyses, it is important to remember that some compounds often occur in association one with another on HS-GC (Table 5). Analysis of metabolites in urine may extend the time in which exposure may be detected but, of the compounds commonly abused, only toluene, the xylenes, and some chlorinated solvents, notably trichloroethylene, have suitable metabolites (Table 4).

Table 5 Associated volatile compounds: headspace gas chromatography

Compound	Associated compound(s)
Acetone	Butanone and higher ketones in ketoacidosis, 2-propanol (metabolite, rare)
BCF	HCFC 11
Butane	Butanone (metabolite ^a), isobutane, 2-butanol (metabolite ^a), propane
Cyclohexanone	Cyclohexanol (metabolite)
Dimethyl ether	HCFC 22 or other fluorocarbons
Ethanol	Propanols and higher order alcohols if bacterial fermentation has occurred; methanol or other volatile poisons if denatured alcohol has been consumed
Ethyl acetate ^b	Ethanol (metabolite)
Ethylbenzene	(See xylenes below)
HCFC 11	BCF, HCFC 12
HCFC 12	HCFC 11
HCFC 22	Dimethyl ether
Halothane	2-Chloro-1,1-difluoroethylene, 2-chloro-1,1,1-trifluoroethane (metabolites ^a)
Isobutane	Butane, 2-methyl-2-propanol (metabolite ^a), propane
Isobutyl nitrite ^b	2-Methyl-1-propanol (degradation product)
Isopentyl nitrite ^b	3-Methyl-1-butanol (degradation product)
Isopropyl nitrite ^b	2-Propanol (degradation product)
Methyl acetate ^b	Methanol (metabolite)
Propane	Butane, isobutane, 2-propanol (metabolite ^a)
2-Propanol	Acetone (metabolite)
1,1,1-Trichloroethane	Isopropyl nitrate (stabilizer ^a)
2,2,2-Trichloroethanol	Trichloroethylene
Trichloroethylene	2,2,2-Trichloroethanol (metabolite), chloroform (possibly from thermal degradation of trichloroacetic acid (metabolite) <i>in vitro</i> at temperatures above approximately 45 °C)
Xylenes	<i>o</i> -, <i>m</i> -, and <i>p</i> -xylene occur together in technical xylene, <i>m</i> -xylene predominating. Ethylbenzene also contaminant in technical xylene

See Table 1 for full chemical names of certain compounds.

^aRarely found.

^bParent compound not normally detected in blood.

Chronic petrol 'sniffing' has been diagnosed by the measurement of blood lead concentrations, or by detection of aromatic components such as toluene and ethylbenzene. Abuse of the fluorinated anesthetic methoxyflurane has been detected by measuring serum and urine fluoride ion. With some petrois and other complex mixtures such as petroleum ethers (Table 1), however, the blood concentrations of the individual components are often below the limit of detection of HS-GC methods even after significant inhalational exposure.

Detection of a volatile compound in blood does not always indicate VSA or occupational/environmental exposure to solvent vapor. Acetone and some of its homologs may occur in high concentrations in ketotic patients. Large amounts of acetone and butanone may also occur in blood and urine from children with β -ketothiolase deficiency. In addition, acetone is the major metabolite of 2-propanol in man (Table 4). Conversely, 2-propanol has been found in blood from ketotic patients. Other ketones may also give rise to alcohols *in vivo*.

Cyclohexanol, for example, is the principal metabolite of cyclohexanone in man. Other compounds such as halothane or chlorobutanol may be used in therapy, or inadvertently added to the sample as a preservative. Ethyl chloride may give a peak resembling ethanol on GC-FID.

Use of aerosol disinfectant preparations when collecting specimens may contaminate the sample if an aerosol propellant is used. Contamination of blood samples with ethanol or 2-propanol may also occur if an alcohol-soaked swab is used to cleanse skin prior to venepuncture. Contamination with technical xylene (a mixture of *o*-, *m*-, and *p*-xylene together with ethylbenzene) has been found in blood collected into Sarstedt Monovette Serum Gel blood collection tubes; contamination with toluene (up to 22 mg l⁻¹), 1-butanol, ethylbenzene, and xylene was found in batches of these same tubes. Contamination with 1-butanol or 2-methyl-2-propanol occurs commonly in blood collected into tubes coated with EDTA. Care should be taken when handling frozen tissue prior to analysis as any compounds present in ambient air may condense on the cold surface and give rise to false positives. Processing blank frozen tissue can help control for this possibility.

Data to aid the interpretation of quantitative analytical results for primarily whole blood for a range of solvents, metabolites, and so on are given in Table 6. As a general rule, whole blood concentrations in the range of 10–100 mg l⁻¹, perhaps more, are attained during VSA and may be expected in postmortem specimens. However, there is usually a big overlap in the blood concentrations of volatile compounds attained after workplace exposure and as a result of deliberate inhalation of vapor. Similarly, the blood concentrations of volatile anesthetics attained during anesthesia may far exceed those found in VSA-related deaths. This reflects the fact that VSA-related deaths are often sudden and perhaps multifactorial (indirect toxicity such as inhalation of stomach contents, possible hypoxia, catecholamine release, etc., as discussed earlier), and that toxicity varies greatly depending on the route and intensity of exposure (blood concentrations may not necessarily reflect concentrations in vital areas of the brain or heart). Moreover, there is always the possibility of loss of volatile analytes from blood or other biological samples prior to the analysis.

The interpretation of case data involving chloroform may be particularly difficult. In addition to sometimes being present in drinking water at low concentrations (following chlorination of drinking water), chloroform is found in a variety of medicinal preparations, in cigarette smoke, soft drinks, margarines, and in swimming pools. A further possible source of chloroform on HS-GC is from thermal decomposition of trichloroacetic acid at temperatures above 40 °C or so. Trichloroacetic acid is a metabolite of several compounds including the solvent trichloroethylene (Table 4) and the drugs chloral hydrate, dichloralphenazone, and triclofos (2,2,2-trichloroethanol dihydrogen phosphate). Trichloroacetic acid has a half-life in blood of 3–5 days and thus may be detected for a relatively long time after exposure to, or ingestion of, a precursor. Trichloroacetic acid plasma concentrations of up to 40 mg l⁻¹ have been reported after occupational exposure to trichloroethylene vapor.

In 25 Caucasian adult women in Florida, USA, over a period of 6 months average plasma chloroform concentrations were generally less than 25 µg l⁻¹, but in two subjects, plasma

chloroform concentrations of 2.9 and 4.0 mg l⁻¹, respectively, were found during routine sampling. All subjects were carefully screened to exclude occupational and recreational exposure to chloroform and other compounds that could give rise to chloroform on HS-GC. At the other extreme, postmortem blood chloroform concentrations in fatalities involving this agent have been reported as 10–50 mg l⁻¹. During anesthesia, blood chloroform concentrations of 50 mg l⁻¹ or more were expected (Table 6).

It is well known that ethanol may be both produced and metabolized by microbial action in biological specimens. Higher-order alcohols (fusel oils) may also be produced as a result of fermentation. Dimethyl sulfide is a common product of putrefaction. Small amounts of hexanal may arise from degradation of fatty acids in blood on long-term storage even at –5 °C to –20 °C. Hexanal is resolved from toluene on the SPB-1 capillary GC system discussed earlier, but resolution may be lost if an isothermal quantitative analysis is performed. Interference from hexanal is only likely to be important, however, if very low concentrations of toluene (0.1 mg l⁻¹ or less) are to be measured.

For very volatile compounds such as propane and butane, detection followed by an estimate of the quantity present in the sample at the time of the analysis (low, high, similar to that seen in other VSA-related deaths, etc.) is often all that can be attempted. In some deaths attributed to the abuse of LPG, only butane, isobutane, and propane are detected on HS-GC of postmortem blood. In other cases, these three compounds may occur together with 2-propanol, acetone, 2-methyl-2-propanol, 2-butanol, and butanone (Figure 3). By analogy with the metabolism of hexane (Table 4), these additional compounds probably arise from the metabolism of the butanes and propane (Figure 4).

The alkyl nitrites (e.g., isobutyl nitrite, isopropyl nitrite) are a special case in that (a) they are extremely unstable and break down rapidly *in vivo* to the corresponding alcohols, and (b) they usually also contain other isomers such as butyl nitrite or propyl nitrite. Any products submitted for analysis will usually contain the corresponding alcohols as well as the nitrites. Methemoglobinemia usually only occurs when exposure has been substantial, for example, after ingestion.

In the occupational setting, blood toluene concentrations after exposure up to 127 ppm toluene (UK Occupational Exposure Limit at the time 100 ppm) for 8 h ranged between 0.4 and 6.7 mg l⁻¹. After brief exposure, only signs of moderate intoxication such as slurred speech and unsteady movements have been associated with blood toluene concentrations as high as 30 mg l⁻¹. Blood toluene concentrations in samples from 132 patients who were thought to have engaged in VSA ranged from 0.2 to 70 mg l⁻¹, and were above 5 mg l⁻¹ in 22 of 25 deaths. On the other hand, 13 patients with blood toluene concentrations greater than 10 mg l⁻¹ were either asymptomatic or only mildly intoxicated (headache, nausea, vomiting, and/or drowsiness), although these manifestations of toxicity can lead to 'indirect' acute VSA-related death. Similarly, after exposure to 350 ppm 1,1,1-trichloroethane (UK maximum exposure limit at the time) for 1 h, the mean blood 1,1,1-trichloroethane concentration was 2.6 mg l⁻¹. Blood 1,1,1-trichloroethane concentrations ranged from 0.1 to 60 mg l⁻¹ in samples from 66 patients suspected of VSA, 29 of whom died. There was a broad relationship between

Table 6 Solvents and other volatile compounds: simple guide to the interpretation of analytical toxicology results

Analyte	'Therapeutic' or 'normal' whole blood concentration (less than)	Whole blood concentration associated with serious toxicity ^a	Relative molecular mass
Acetaldehyde	0.2 mg l ⁻¹	(Not known)	44.1
Acetone (see also 2-propanol ^b) (urine)	10 mg l ⁻¹ (1 g l ⁻¹ in ketosis) 10 mg l ⁻¹ (2 g l ⁻¹ in ketosis) 80 mg l ⁻¹ ^c	(Not known)	58.1

^eSuggestive of recent toluene exposure, but dietary benzoate may give elevated hippurate excretion.

Figure 4 Summary of the metabolism of butane, isobutane, and propane in man.

blood 1,1,1-trichloroethane concentration and the severity of poisoning, but as in the case of toluene, there was a big overlap between the blood concentrations encountered in fatalities and those attained after occupational exposure.

Some 80% of a dose of toluene is converted to hippuric acid (Table 4), which is excreted in urine. Similarly, more than 90% of a dose of xylene is metabolized to methylhippuric (toluric) acids. The principal isomer found in urine is 3-methylhippurate, from *m*-xylene (Table 1). Methylhippurates are not normal urinary constituents, but hippuric acid may arise from the metabolism of benzoates in medicines and also from foods containing primary phenols and simple aromatic acids such as bilberries and cherries. Hippurate and methylhippurate excretion is often expressed as a ratio to creatinine. Occupational exposure to toluene can give rise to ratios of up to 1 g hippurate per gram creatinine or more; in patients suspected of VSA, a ratio of more than 1 g hippurate per gram creatinine strongly suggests, but does not prove, toluene exposure. Measurement of urinary *o*-cresol has been proposed as an alternative means of monitoring toluene exposure selectively, particularly in occupational circumstances, but the assay procedure is relatively complex and is not widely used.

Introduction

Forensic toxicology concerns the analysis of biological specimens (fluids and tissues) for the presence and, often, the concentration of drugs and poisons. The results of the analyses must be correlated with the circumstances of the case to determine what role, if any, the detected substances played. This correlative function is commonly called interpretation. This article will examine the three major subspecialties of forensic toxicology and the various factors that enter into the interpretation process in each.

The forensic toxicology laboratory exists for the sole purpose of providing interpretable analytical data. Therefore, the analytical strategy is designed with anticipation of the need for later interpretation. The most appropriate specimens should be analyzed by sensitive, specific, and quantitatively accurate and precise techniques to yield reliable data upon which to base opinions. The toxicologist must be absolutely certain that the analytical data are accurate. Furthermore, the samples must be properly preserved and clearly traceable to the subject of the investigation by an unbroken chain of custody, and handled and stored with a level of security sufficient to preclude tampering.

The choice of specimen(s) and the scope of analysis are determined largely by the purpose of the investigation. Modern forensic toxicology can be divided into three major categories: forensic urine drug testing (FUDT), human performance toxicology, and postmortem toxicology. FUDT seeks evidence of illegal drug use by current or prospective employees; human performance toxicology attempts to determine whether the subject was impaired or intoxicated at some specific time by analyzing specimen(s) collected later; and postmortem toxicology investigates the role of drugs and poisons in causing or contributing to the subject's death. Each presents specific requirements and challenges for the interpreting toxicologist.

Forensic Urine Drug Testing

FUDT, also known as workplace drug testing, has as its goal the minimization of drug abuse in the workplace. This goal is accomplished by intimidating potential drug users through fear of detection and by elimination of drug users from the workforce through treatment or discharge. As most employees are not suspected of any wrongdoing, the sampling process is designed to be minimally intrusive. Urine is usually the specimen of choice, although hair and sweat are sometimes used. To control the cost of analysis, FUDT programs restrict the scope of analysis to the drugs deemed most dangerous by virtue of their addictive nature, illegality, abuse liability, or potential harm to the employees' health or productivity. The most commonly included drugs are methamphetamine, amphetamine, cocaine, marijuana, opiate narcotics (morphine, codeine, heroin), and phencyclidine (PCP). Effective October 2010, methylenedioxymphetamine, methylenedioxyamphetamine ('Ecstasy'), and methylenedioxyethylamphetamine were added to the list of substances that must be tested for under US-regulated Substance Abuse and Mental Health Services Administration and Department of Transport drug testing. For nonregulated drug testing, other drugs such as barbiturates, benzodiazepines (e.g., diazepam and alprazolam), and lysergic acid diethylamide (LSD) may be added if desired or their use is perceived to be common in a particular geographic area.

In workplace drug testing, the only issue is whether or not the subject of the test illegally used a controlled drug. The drug testing is usually performed on urine. If a drug or drug metabolite(s) is conclusively identified in a properly collected sample, at a concentration that is equal to or greater than the cutoff for the assay, then the person who provided the urine is presumed to have used the drug. However, legitimate questions may be raised about whether ingestion was intentional or took place unknowingly. Such questions are often referred to a

physician trained in interpretation of drug testing reports, a medical review officer (MRO), but they may also be asked of the toxicologist. The toxicologist or the MRO may be able to comment on the reasonableness of arguments offered in defense of one who tested positive for a drug. Above all, unbiased interpretation must include consideration of alternative explanations for apparently incriminating findings.

First, the toxicologist or MRO must be aware of circumstances that can produce positive tests in a person who has not abused the drug (Table 1). For example, research has shown that passive exposure to marijuana smoke does not yield urinary concentrations of Δ^9 -tetrahydrocannabinol metabolites above 40 ng ml⁻¹. However, taking dietary supplements containing hemp seed oil or eating hemp seed confections can cause readings over 200 ng ml⁻¹. Poppy seeds contain traces of morphine sufficient to cause a positive drug test if poppy seed pastries are eaten. Moderately high urine morphine concentrations have been obtained in controlled experiments in which human volunteers provided urine samples for opiate analysis after consuming poppy seed pastries. Testing for the alkaloid, thebaine, derived from poppy seeds, may help distinguish food from pharmaceutical morphine. Several pharmaceuticals contain, or are metabolized to, the 'l' isomer of methamphetamine (i.e., l-deoxyephedrine; e.g., in Vick's Inhaler™), rather than the controlled 'd' isomer. Routinely applied confirmatory tests cannot distinguish between optical isomers, but chiral separation columns or derivatives can. Such definitive testing may be required if someone challenges a positive urine test for methamphetamine. Another commonly reported explanation for positive urine drug test results is the subject's unknowing consumption of a food or beverage containing a drug that someone else added surreptitiously (e.g., marijuana brownies). The testing methods are sufficiently sensitive to detect excretion products from doses of drug that may be too small to produce observable symptoms. The possible motivation for someone to administer the drug should be considered, as well as the opportunity to do so without detection. Women sometimes allege that they were exposed to a drug such as cocaine through transfer of semen from a drug-using sex partner; however, the amount of cocaine in semen of a user has been measured and is insufficient to produce a positive urine test if ingested. Some people have suggested that their cocaine-positive drug test resulted from handling contaminated money. The amount of

cocaine found in US currency is too small to cause a positive test by dermal absorption, but a single cocaine particle falling into the sample container from the subject's hand could produce a positive result. To prevent contamination, test subjects are often required to wash their hands before providing a urine sample.

Human Performance Toxicology

Human performance toxicology deals with the effects of alcohol and other intoxicating substances on a subject's ability to drive a motor vehicle or engage in other potentially hazardous activities. When impairment, rather than use, is the issue, more information is needed for interpretation. The presence of drug or metabolites in urine is useless for demonstrating impairment. At best, finding an intoxicating substance in urine can explain the source of obvious symptoms of impairment. The concentration of drug and its active metabolite(s) in blood is important, but other factors must also be considered. Individual variability and tolerance can affect the degree of impairment at any given blood drug concentration. Combinations of drugs can interact to increase or decrease impairment. For most drugs, a relationship between drug concentration and performance impairment has not been established. Therefore, evidence for interpretation should include the subject's blood concentrations of all drugs capable of causing impairment, as well as evidence that the subject was impaired. The toxicologist familiar with the behavioral effects of drugs may be able only to offer an opinion that the observed symptoms are consistent, or not consistent, with the effects of the detected drugs. However, to infer that because a drug was present, regardless of concentration, the subject must have been impaired without having evidence of symptoms of intoxication is speculation, not objective interpretation.

The extent to which drug testing is performed on drivers varies considerably, depending on the particular jurisdiction. For many police forces, testing may be limited to breath alcohol measurement. Where testing for drugs is performed (driving under the influence of drugs programs), urine or blood has traditionally been collected. The problem with urine is that some drugs can be detected for days after last use and it is difficult or impossible to relate positive results to impairment without the corroboration of observed behavior. Blood is more useful, but testing is more difficult to perform and the collection of blood is considered 'invasive.' For those reasons, the collection and analysis of saliva have become common in many countries. Although there are analytical challenges for the analysis of saliva, it is relatively easy to collect (there are commercial kits available), and in most instances, a positive drug finding can be more easily related to recent use.

Drug Recognition Expert Programs

Drug recognition expert (DRE) programs, such as that sponsored by the US National Highway Traffic Safety Administration, can provide valuable documentation of intoxication. In DRE programs, trained observers examine subjects suspected of being intoxicated, and record their observations in a

Table 1 Innocent causes of positive urine drug tests

Drug	Source
Marijuana	Hemp seed oil or hemp seed confections
Cocaine	Coca tea, maté de coca, may be imported from South America and has been available in health food stores in the past
Morphine, codeine	Poppy seed pastry – contains morphine and codeine
Amphetamine	Metabolism of medications, for example, clobenzorex
Methamphetamine	Nasal inhalers: l-deoxyephedrine = methamphetamine; metabolism of medications, for example, deprenyl = selegiline

standardized format. The examination includes physiological symptoms (e.g. pulse, respiration, pupil responses, and others), physical tests of coordination and balance, and tests of mental agility, memory and perception. Finally, an algorithmic approach is applied to the observations to place symptom patterns into eight categories: not impaired, or impaired by sedative, stimulant, narcotic, hallucinogen, marijuana, PCP-like or volatile inhalant substances. If the subject is examined while symptoms are present, the documentary evidence can be evaluated in conjunction with results of toxicological analyses. The forensic toxicologist may then be able to offer opinions on the cause-and-effect relationship of the observed behavior or symptoms and the detected intoxicants. Research has shown accuracy rates in the range of 50–80% for DRE examinations, depending upon the drug category and the examiner's training and experience. Therefore, DRE reports must always be confirmed by laboratory analysis before any punitive action, such as conviction for driving while intoxicated, can be justified.

Postmortem Toxicology

Because of their variety and complexity, postmortem toxicological investigations provide the greatest challenges for the interpreting toxicologist. The questions that may be raised in a death investigation may be the same as those involved in workplace drug testing or human performance toxicology, but often the postmortem toxicologist must deal with far more complicated issues. To do so requires not only a familiarity with principles of pharmacology, physiology, biochemistry, and anatomy, but also an awareness of pathological changes associated with toxicity and postmortem changes affecting drug concentrations. Knowledge of factors such as the behavioral effects of drugs and the lifestyle of drug-using subcultures can help in understanding and explaining some aspects of a case.

In postmortem toxicology, interpretation is a thought process that begins with the initial case review and guides the analytical strategy that culminates with the toxicologist forming opinions regarding the involvement of drugs or other substances in the death of an individual. The first question that must be addressed is what, if anything, was ingested by the deceased? The answer lies in the outcome of a thorough toxicological analysis that is capable of detecting relevant (i.e., therapeutic or subtherapeutic) concentrations of any substance that could realistically be present. The extent of the search is governed, in part, by the other aspects of the investigation. If there is a strong suspicion of a drug or poison, then the toxicologist must search more diligently than if there is no such suspicion. A negative result must be interpreted from an understanding of the sensitivity of the analytical method. It implies that the analyte targeted by the test was not present or, if present, was at a concentration below the detection limit. If methods of sufficient sensitivity are used, negative findings mean that either nothing was ingested or something outside the scope of analysis was involved. Knowledge of the chemical properties of various drugs and poisons and of the capabilities and limitations of available analytical techniques is essential to the determination of whether the analysis is capable of detecting all targeted substances.

When drugs or other toxic substances are detected in body fluids or tissues, the toxicologist must gather additional data in an effort to determine what role, if any, the detected substances played in the events leading to death. In some cases where the cause of death is manifestly obvious, such as accidental, the result of assault, or self-inflicted trauma, the issue becomes one of the impairing or intoxicating effects of drugs, including alcohol (behavioral toxicity). Substances lacking psychoactivity are usually incidental to the investigation, unless they could have affected survivability. In cases of death attributable to natural disease, the toxicologist is concerned with substances that can exacerbate preexisting illness. Examples include cocaine and other sympathomimetic agents with heart disease or berry aneurysms, and nonselective β -adrenergic blocking agents in patients with asthma. Other potential issues for the toxicologist include adverse interactions of therapeutic drugs and unsuspected intentional overdose in an otherwise seriously ill person. In some cases, such as death from epileptic seizures, it may be important to document whether the deceased was compliant with life-sustaining therapy.

When a toxic mechanism of death is suspected from the findings of the investigation and autopsy, the toxicologist is asked to identify the offending substance(s) and, insofar as possible, to determine the route and mode of entry. Was ingestion accidental or intentional? Was enough drug or poison present to cause death, and was it ingested acutely or cumulatively? If multiple substances are detected, do they possess additive or synergistic toxic activity?

Drug Interactions

If multiple substances are identified, some may be unrelated to the cause of death, whereas others may have interacted, resulting in fatal consequences. Drugs with similar toxic mechanisms, such as respiratory depression or cardiovascular stimulation or depression, can be expected to contribute additively or synergistically to the net toxic effect. For example, ethanol, benzodiazepines, and opiates all have respiratory depressant activities at toxic concentrations. In combination, they can produce serious or fatal respiratory depression, even when the individual drugs are present in subtoxic concentrations. The calcium channel blocker, verapamil, and β -adrenergic antagonists, such as propranolol or timolol, may both be prescribed for migraine headaches or to lower blood pressure. When combined, verapamil and beta blockers can sometimes lead to fatal cardiogenic shock and can even cause the heart to stop beating. It is sometimes apparent that one drug exerted the predominant effect, without which the death would not have occurred. This is often the case with heroin toxicity. Other drugs, such as alcohol, benzodiazepines, cocaine, or other opiates, if present, would be expected to contribute to toxicity, but usually would not be lethal without the addition of heroin.

Postmortem Changes Affecting Toxicology

During life, drugs are differentially concentrated in the various organs to levels that may be orders of magnitude higher than that in blood. By definition, the higher the proportion of a drug that is sequestered outside of the blood volume, the higher is the 'volume of distribution' of that particular drug.

The liver, heart, and lungs are among the tissues known to sequester various drugs. After death, the physiological and chemical conditions that maintain the differential begin to degrade, causing such changes as a decrease in blood pH. These physiological changes cause protein binding to decrease, allowing drugs to diffuse out of tissues into blood – a process often referred to as postmortem redistribution (PMR). Drugs with a relatively high volume of distribution are substantially more affected by PMR than drugs like benzodiazepines that have a volume of distribution closer to 1. Therefore, blood collected from the vena cava is likely to contain excess drug released by the liver, as well as any drug freshly absorbed from the gastrointestinal tract. Heart blood, “chest cavity blood,” or aorta blood may contain drug released by the heart tissue, lungs, and liver and, potentially, may be contaminated by stomach contents. A therapeutic concentration of drug can quickly rise into the “toxic” or “lethal” range on tables derived from clinical observations of living subjects. Large differences in drug concentrations are often found when blood from these visceral sites is compared with blood from a peripheral site, such as femoral or subclavian vein. It is now recognized that analysis of peripheral (e.g., femoral) blood provides data that are closer to the blood concentration that existed at the moment of death. Nonetheless, there is growing evidence that for some drugs, even properly collected peripheral blood may be subject to significant PMR. Therefore, the toxicologist cannot simply compare a drug’s concentration in blood with published clinical data of therapeutic, toxic, and lethal concentrations. To do so would probably lead to erroneous conclusions. Postmortem drug concentrations should be compared with postmortem data on the same site from cases of known drug toxicity and from cases where toxicity was not involved. Such an approach will often help to distinguish elevated from normal drug levels. Analysis of tissue such as liver frequently reveals very high concentrations of many drugs in overdose cases. However, care must be taken to differentiate acute ingestion of an overdose from accumulation (buildup) of a drug in the body due to impaired metabolism or excretion. Measuring the total amount of unabsorbed drug remaining in the stomach after death can support the conclusion of toxicity due to ingestion of an acute overdose if a quantity representing more than a normal dose is found. Finding a trace of drug in the stomach does not prove an oral route of administration, because most drugs diffuse from the blood into the stomach. The same is true when cocaine is detected in a sample obtained by swabbing the nasal passages. A small amount of cocaine will pass from blood to the nasal secretions regardless of the route of administration. Only if a relatively large amount of cocaine is found can one conclude that it was taken intranasally.

While PMR may elevate drug concentrations in blood, some drugs continue to be metabolized after death. Enzymes, especially esterases, that do not require oxygen or consume energy, remain active and hydrolyze susceptible drugs, including cocaine, heroin, and a heroin metabolite, 6-monoacetylmorphine. The net effect of the competing processes, redistribution and metabolism, on drug concentrations in postmortem specimens is unpredictable.

Ethanol can be produced by fermentative microorganisms during putrefaction so that concentrations in specimens from a decomposing body are not representative of the blood alcohol concentration at the time of death. In many cases where

ethanol is found in a decomposed body, it may be said that the deceased probably consumed some alcohol before death, but when ethanol concentrations are lower than 0.1 g dl^{-1} in a severely putrefied body, the alcohol may have been entirely produced by postmortem fermentation. Even higher values of postmortem ethanol production (over 0.2 g dl^{-1}) have been reported. If available, analysis of vitreous humor (eye fluid) for ethanol may help determine whether the person consumed ethanol while they were alive. Vitreous humor can remain sterile for several days after death, and therefore fermentation due to the action of microorganisms cannot occur.

Putrefaction can also affect interpretation of carbon monoxide measurements in postmortem blood. The percent of total hemoglobin combined with carbon monoxide (i.e., carboxyhemoglobin) is usually measured spectrophotometrically. A decomposition product, sulfmethemoglobin, has an absorption spectrum that overlaps that of carboxyhemoglobin. Putrefaction will elevate the carbon monoxide reading with most methods, but may depress it with others. Therefore, the toxicologist must understand the effects of sulfmethemoglobin on the method whose result is being interpreted to know whether the reading is artifactually high or low in a decomposed sample. In severely decomposed blood, it may not be possible to obtain a usable carboxyhemoglobin measurement. While direct measurement of carbon monoxide in a sample is possible using some methods, the problem remains that interpretation of the concentration needs to be related back to the percentage saturation of carbon monoxide in hemoglobin. In a decomposed or heat-denatured blood sample, the hemoglobin may be all but destroyed.

Correlative Information

The presumption of toxicity must be further evaluated, taking other physical and factual evidence into consideration. The terminal events, medical and social history, and autopsy findings must be correlated with drug concentration data. Tolerance from chronic use of a drug such as morphine can raise the threshold for therapeutic effect into a range that would be lethal to a nontolerant individual. Although not specific, pulmonary edema and congestion revealed by autopsy can lend support to a suspicion of drug toxicity due to respiratory depression. Even though many pathological changes in the body are not specifically associated with drug toxicity, their presence is supportive, whereas their absence would indicate that drug toxicity was not responsible for the death. Some diagnoses, such as sudden infant death syndrome, and some cardiac deaths are justified only after other causes, including poisoning, are excluded.

Observations from the death scene, such as a body posture that restricts respiration or a plastic bag over the head, can explain why some people die with drug concentrations that, while elevated, would not normally be expected to cause death. Drug intoxication in these cases would be one factor that prevents the victim from restoring normal respiratory exchange. Elevated body temperature measured at a death scene can be related to a disturbance in thermoregulatory homeostasis that is often associated with toxicity due to cocaine, amphetamines, neuroleptics, and some other drugs.

Witnesses to a death can sometimes provide valuable information about the behavior of the deceased and the terminal

symptoms. Reports of bizarre and violent behavior followed by sudden death are evidence of excited delirium, which may be attributable to cocaine or amphetamines if supported by analytical documentation of their presence. Concentrations are usually below the range considered to be lethal, so the behavioral evidence may be critical in arriving at a correct conclusion. Drug paraphernalia found at a death scene raises or supports a suspicion of drug toxicity, which can be confirmed by autopsy and toxicological analysis.

When a hospitalized victim of trauma or poisoning dies in spite of treatment, medical records documenting the progression of symptoms can sometimes be correlated with postmortem toxicology data. The mechanism of toxicity of the drugs or poison, such as the electrocardiographic abnormalities caused by tricyclic antidepressants, should be manifest in the reported symptoms and observed physical findings. This becomes especially important when life support efforts delay the terminal event, allowing the responsible toxin to be eliminated to a point that postmortem concentrations are too low to be detected, or, if detected, to be considered toxic without the additional supporting evidence. In some jurisdictions, the postmortem toxicology laboratory obtains specimens of blood, urine, and stomach contents collected soon after the patient's arrival at the hospital. These antemortem specimens sometimes yield the only reliable evidence of the state of intoxication of the deceased at the time of admission. For example, drugs administered by physicians, including morphine, haloperidol, lignocaine (lidocaine), atropine, and others, will not usually be found in admission specimens, whereas drugs taken prior to hospitalization will.

Drug Metabolism (Biotransformation)

Whenever a foreign substance is introduced into the body, drug-metabolizing enzymes act upon it to accelerate its elimination. Cytochromes of the P₄₅₀-class, esterases, and other hydrolases introduce polar functional groups, such as hydroxyl, carboxyl, or amino, and conjugating enzymes, including glucuronyl transferases and sulfotransferases, link the polar functional groups to highly water-soluble polar molecules, glucuronic acid or sulfate, in order to form water-soluble conjugates that are readily excreted.

Biotransformation of drugs and poisons is a factor that is frequently considered in the interpretation process. Drug metabolites are often pharmacologically inactive, but some retain activity or possess activity different from the parent drug. In some cases, such as aromatic amines (2-naphthyl amine, 4-aminobiphenyl), halogenated hydrocarbons (chloroform, carbon tetrachloride), and acetaminophen, metabolism yields toxic products. Some biotransformation reactions are subject to induction or inhibition by certain drugs so that the rate of metabolism of other drugs or poisons is increased or decreased. Thus, if an inhibitor of a specific enzyme is present, concentrations of that enzyme's substrate can rise to toxic levels, or an inducer can cause accumulation of a toxic metabolite or can lower a drug's concentration to an ineffective level. An awareness of metabolic interactions and biotransformations can help the toxicologist distinguish between intentional and accidental intoxication.

The postmortem toxicology laboratory often quantifies both parent drug and its principal metabolite(s). The ratio of

parent drug to metabolite concentrations can indicate whether ingestion was chronic or acute. Metabolites of many drugs accumulate in the body with chronic administration. Conversely, an acute overdose may yield only a small amount of metabolite before death occurs. Furthermore, drugs such as propoxyphene and meperidine that are converted to toxic metabolites may produce toxicity by virtue of accumulation of the metabolite during chronic administration.

Pharmacokinetics

The science of pharmacokinetics describes the time course of drug action in terms of the processes of absorption, distribution, and elimination. The onset of drug action is determined, first, by the rate of distribution to the site of action. The action is terminated by the elimination of the drug via metabolism and excretion.

Although the concentration of drug in the postmortem blood, tissues, or urine cannot usually be related to pharmacokinetic parameters determined in living humans, the clinical data are still valuable to the postmortem toxicologist. For example, a drug's elimination rate can usually be expressed in terms of its half-life ($t_{1/2}$ elim.), which is the length of time required for the concentration to decline to half of its initial value in a process following first-order kinetics (i.e., the rate of elimination is proportional to drug concentration at any time point). Approximately 99% of the drug will be eliminated by 6–7 half-lives after its distribution is complete. Usually absorption and distribution occur much faster than elimination. Therefore, if a drug is detected in postmortem blood, it was probably taken within 6–7 half-lives prior to death.

The distribution pattern between blood and other biofluids and tissues can also be useful for interpretation. Probably the drug whose pharmacokinetic behavior is best understood is ethanol. In postmortem toxicology laboratories, ethanol is usually measured in different body fluids from the same individual to facilitate interpretation. At or near equilibrium, the concentration of ethanol in vitreous humor (eye fluid) is usually about 15–20% higher than that in whole blood. If both fluids are analyzed and blood has higher ethanol concentration than vitreous, then by the pharmacokinetics of ethanol (Figure 1), the individual was in the absorption phase, or the sample was contaminated with ethanol from stomach contents or putrefaction. Conversely, if the vitreous ethanol concentration is much higher than the blood, the blood sample may have been diluted, and the toxicologist should consider the site of collection and whether intravenous fluids were administered prior to death. To resolve discrepancies, other samples may be analyzed, including blood from another site, bile, brain tissue, urine, and stomach contents. A pattern should emerge from the data to explain the pharmacokinetic state at the time of death.

Behavioral Toxicity

Psychoactive drugs, both licit and illicit, can cause alterations in perception, judgment, coordination, mood, and information processing. In cases involving violence or accidental trauma, when such drugs are detected in the body of the deceased, questions inevitably arise regarding the role of the drug(s) in precipitating the fatal event. The issues are similar to those in human performance toxicology, except that specimens

Figure 1 Hypothetical pharmacokinetic curves for ethyl alcohol in blood (—) and vitreous humor (---). Note that the vitreous alcohol concentration is lower than that in the blood during the absorption phase, but it exceeds the blood alcohol concentration during elimination.

are usually collected postmortem rather than from a living subject. Therefore, drug concentrations must be considered in light of postmortem changes, and impairment or intoxication must be deduced from factual evidence (eyewitnesses) and physical evidence available at the scene where the fatal incident occurred. For example, a motor vehicle crash investigation may discover evidence of driver error, and later toxicological analysis reveals elevated blood alcohol or a high concentration of a drug with the potential to cause impairment. Similarly, when a person becomes excited, violent, and irrational, then disrobes, breaks objects, struggles with police, and suddenly becomes unresponsive and dies, a finding of even a few hundred nanograms per milliliter of cocaine in the blood of the deceased suggests that the death or behavior can be attributed to cocaine-induced excited delirium. This opinion is supported by a documented high postmortem body temperature and a

postmortem blood benzoylecgonine concentration of several thousand nanograms per milliliter.

Because of the many factors affecting measured postmortem drug concentrations, such data can rarely serve as the sole basis for interpretation. They must be correlated with evidence from the autopsy and with information gathered by police, and other investigators. Conversely, inferences and suspicions derived from autopsy and investigation must be refined and confirmed through toxicological studies. Only then can reliable opinions be formulated regarding the role of drugs or poisons in a death investigation.

Introduction

Toxicological analysis, be it forensic, clinical, environmental, workplace, drug abuse, or doping control, principally involves the detection of chemical substances potentially harmful to living organisms. Chemical analysis is used to detect the presence of these substances, measure their concentrations, and interpret this in relation to their relative toxicity. Paracelsus (1493–1541) said:

All things are poison and nothing is without poison, only the dose permits something not to be poisonous. (Wikipedia)

Our society is surrounded by a large number of compounds that are potentially poisonous (including chemicals, drugs, pesticides, common household products, etc.) and the task of the toxicologist is a formidable one to attempt to cover as many of these substances as possible in a toxicology screen.

Forensic toxicology involves the use of a number of analytical techniques, which can include or exclude the presence of these compounds. For most laboratories that may be analyzing hundreds or thousands of samples per year, it is not practical to try and cover all of these compounds and an appropriate approach is to screen for the common drugs of abuse, prescription and nonprescription drugs in the first instance, and then carry out any specific analyses that may be indicated by the case

history. In most forensic toxicology laboratories, a general drug screen includes a range of immunoassay tests, alcohol analysis (either by direct liquid injection or headspace gas chromatography (GC)), and a broad-based GC or high-performance liquid chromatography (HPLC) procedure as shown in [Figure 1](#).

Laboratories would then have a suite of specific methods for the detection of nonroutine compounds (e.g., headspace analysis for volatile organic compounds, pesticides, and rodenticides) and drugs not covered by their general screen due to sensitivity (e.g., lysergic acid diethylamide (LSD) or buprenorphine) or specific extraction techniques (e.g., quaternary ammonium compounds). Thin layer chromatography (TLC) may also be used in some laboratories, but has largely been replaced with other forms of chromatographic separation. Nitrogen–phosphorus detectors (NPDs) are commonly used in GC screening as the large majority of drugs contain nitrogen, whereas many endogenous compounds (fatty acids, cholesterol, and other lipids) are nonnitrogenous. Electron capture detectors (ECDs) have also been used for the screening of halogenated compounds (e.g., many benzodiazepines contain halogens) and provide an extremely sensitive detection method.

Similarly, HPLC systems are often coupled to an ultraviolet (UV) detector or to a photodiode array detector (DAD). With the improvement in technology and the decrease in costs, mass spectrometer (MS) detectors are now increasingly replacing

Figure 1 Flowchart showing common screening procedures.

NPD and ECD in GC systems, and UV and DAD in HPLC systems. There are a number of articles in the literature relating to systematic toxicology analysis (STA).

Sample Selection

It is important in forensic toxicology that the appropriate sample is selected for screening as this will have significant relevance for the interpretation of the results. In cases where it is necessary to only show that a subject has used a drug, it would be more suitable to analyze urine or hair as these samples are more likely to show past exposure to a drug. However, if the presence of a drug is necessary to show the involvement of that drug in the behavior of the subject involved in criminal activity, that is, cause of death, driving under the influence (DUI), then the best samples for analysis would be blood or oral fluid. In postmortem cases, it is also preferable to analyze peripheral blood as this is the least likely site to experience any postmortem changes in drug concentrations and represent more closely the concentration of the drug at the time of death. Some laboratories may choose to screen heart blood as this will contain higher concentrations of the drug and make their detection easier; however, it is important that any further quantitative analysis is carried out on peripheral blood for interpretation purposes. Interpretation of these drug levels should still be made with caution as even in peripheral blood, there may be significant changes in some drug concentrations after death.

A simple guide for sample selection is shown in Table 1.

Immunoassays

Immunoassay in forensic toxicology is primarily used to screen biological samples for presence of drugs or drug classes. It

Table 1 Time frame for drugs in different biological specimens

<i>Specimen</i>	<i>Drug(s) present</i>	<i>Time frame</i>	<i>Interpretation</i>
Blood	Parent/metabolites	Hours	Recent use
Oral fluid	Parent	Hours	Recent use
Urine	Metabolites	Hours/days	Use
Hair	Parent/metabolites	Months	Use

offers a rapid and convenient way of screening large numbers of samples from a variety of different matrices (blood, urine, oral fluid, etc.) for a number of drugs and drug classes. A negative immunoassay result avoids the need for more complicated and expensive analytical procedures. It requires little or no sample preparation although some techniques may require pretreatment of blood or tissue specimens. Any size laboratory can use immunoassay with methods that range from on-site testing for the analysis of a single sample to fully automated systems capable of handling thousands of samples per day. Immunoassays are based on the interaction of the target compound (antigen) with the corresponding antibody. For drug testing, the immunoassay uses an antibody specific for the nominated drug or drug class and a labeled form of the same drug or of the antibody to produce a measurable signal.

Although immunoassays are extremely useful in screening large number of samples, they cannot be used as confirmation of the drug or drug class, and any positive results should always be confirmed by a more specific technique ((gas chromatography–mass spectrometry (GC–MS) or liquid chromatography–mass spectrometry (LC–MS)) that produces an unequivocal identification of the compound.

The basic immunoassay technique involves the competition of a fixed amount of labeled drug with an aliquot of the sample for the specific binding sites on a fixed quantity of antibody. At equilibrium, the proportion of labeled drug molecules bound is inversely proportional to the number of unlabeled drug molecules as shown in Figure 2.

Immunoassays can be divided into two types.

1. Homogeneous immunoassays:

These are assays that do not require separation of the antibody-bound drug from the unbound (free) drug before measurement of the signal. They include assays that rely on optical change (e.g., UV absorption, fluorescence, or luminescence) where there is a difference between the signals from the bound and the unbound labeled drug. Examples of this type of immunoassay are EIA (enzyme immunoassay), CEDIA (cloned enzyme donor immunoassay), FPIA (fluorescence polarization immunoassay), and micro-particle methods.

2. Heterogeneous immunoassays:

These assays require separation of the antibody-bound drug and the unbound drug before measurement of the signal. This is required as there is no difference in the signals from the antibody-bound and the unbound drugs. Examples of this type of immunoassay are ELISA (enzyme linked immunosorbent assay), RIA (radioimmunoassay), and chemiluminescence immunoassays.

There are two distinct advantages of the heterogeneous immunoassays over the homogeneous type. The first

Figure 2 Competitive binding process in immunoassay.

advantage is that as they employ a wash step, this removes any potential endogenous interfering compounds, which may be produced by whole blood or highly discolored urine. This also means that there are no preliminary sample extraction steps required. The second advantage is that these assays have lower limits of detection. This is best illustrated by being able to use whole blood in heterogeneous assays, whereas extraction of the blood sample is often required for homogeneous assays.

Specificity and Cross-Reactivity

It is important with any immunoassay technique to determine how the assay responds to other drugs relative to the drug used as a calibrator. The cross-reactivity of the assay is important as it will determine the suitability of the test. For example, determining *Cannabis* use by the analysis of a urine sample requires the immunoassay to have good cross-reactivity with the major urinary metabolite, Carboxy-tetrahydrocannabinol (THC). However, by contrast, the assay needs to have good cross-reactivity to THC if the samples to be analyzed are oral fluid or hair as the relative parent drug concentration is greater than metabolite in these specimens.

There are many commercial immunoassay kits available and specifications as to their sensitivity and specificity should be available for each kit, so that the laboratory can determine if the test meets its requirements.

Enzyme Immunoassay

EIA can be either homogeneous (Enzyme Multiplied Immunoassay technique or EMIT) or heterogeneous (ELISA) immunoassays.

EMIT is a liquid phase assay based on the enzyme activity of a drug-labeled enzyme and antibodies raised against the drug of interest modulate the activity of the enzyme. In the presence of glucose-6-phosphate, the enzyme reduces nicotine adenine dinucleotide (NAD) to NADH and the resulting increase in absorbance is measured spectrophotometrically at 340 nm. As the amount of drug in the sample increases, there will be a corresponding increase in enzyme activity and an increase in

the rate of NADH production, which will be measured spectrophotometrically by monitoring the $\lambda_{\max}$ at 340 nm.

As EMIT relies on a color change in the solution, it is not suitable for samples such as blood or highly discolored urine without sample pretreatment. Another limitation of the technique as well as interference from other cross-reacting compounds is that, any compound in the matrix that may inhibit the enzyme activity will also affect the result.

ELISA is probably the most commonly used immunoassay in most forensic toxicology laboratories. Commercial ELISA kits are supplied as a dry 96-well microplate with each well precoated with the antidrug antibodies.

ELISA is a heterogeneous, solid-phase assay that requires the separation of reagents. The most common ELISA technique is the competitive immunoassay (Figure 3). In antigen competitive assays, the antibody is bound to the well and labeled and unlabeled antigen compete for the limited number of antibody-binding sites. After the incubation period, an immune complex is formed from the antigen-antibody binding and any unbound antigen is removed by washing. A substrate and chromogen is then added to the immune complex and a reaction between the enzyme and the substrate causes the chromogen to become colored. The more antigen (drug) present in the sample, less the color produced. The reaction is stopped after a preset time by the addition of dilute acid and the color is measured at the $\lambda_{\max}$ at 450 nm. ELISA is a more sensitive technique than EMIT and is less subject to matrix effects. It is regularly used to analyze postmortem blood samples.

Radioimmunoassay

RIA was one of the first heterogeneous immunoassays and the most common type is the antibody-coated tube utilizing γ -emitting I^{125} -labeled antigen. Separation of the bound and free antigen is accomplished by simply decanting the liquid leaving the bound fraction coated to the tube and the resulting radiation measured with a gamma radiation counter. The technique has been largely replaced by the EIA methods as they avoid using radioisotopes.

Figure 3 Competitive immunoassay process.

Cloned Enzyme Donor Immunoassay

CEDIA is a more recent homogeneous immunoassay that uses the binding of an antibody to change the activity of genetically engineered fragments of β -galactosidase from *Escherichia coli* as the enzyme label. The enzyme is present as two inactive fragments, the enzyme acceptor (EA) and the enzyme donor (ED). ED contains a small portion of enzyme missing from the larger EA fragment. Antibodies that bind to the hapten that is conjugated to the ED fragment prevent the reassociating of the enzyme and reduces the enzyme activity. As the amount of drug increases, the amount of bound antibody to the ED fragment decreases resulting in an increase in enzyme activity due to the reassociation of EA and ED. The enzyme hydrolyzes chlorophenol red- β -galactoside (CPR) to chlorophenol red (CPR) and galactoside and the enzyme activity can be measured spectrophotometrically.

Fluorescence Polarization Immunoassay

FPIA is also a heterogeneous immunoassay technique that uses fluorescein-labeled antigen. The labeled antigen can rotate

freely when not bound to an antibody; however, when it is bound, its ability to rotate is dramatically reduced. Light at the excitation wavelength of fluorescein is passed through a polarized filter and as the drug present in the sample competes with the fluorescein-labeled antigen for the antibody, there is a reduction in the amount of fluorescein bound and, therefore, a reduction in the amount of fluorescence through the polarized filter.

Chemiluminescence Immunoassay

This technique is similar to other heterogeneous assays but offers greater sensitivity using chemiluminescence. The signal produced is generated by the emission of light during a chemical reaction and captured by a charged coupled device (CCD) camera. This technique has been developed to assay a range of different drugs and drug classes achieved by attaching specific drug antibodies to discrete test regions on the biochip, which allows the simultaneous screening for many drugs or drug classes in a single sample analysis.

Kinetic Interaction of Microparticles in Solution

Kinetic interaction of microparticles in solution (KIMS) is a homogeneous immunoassay in which the labeled compound is a microparticle with several drug molecules attached. If the sample being analyzed is drug free, then the microparticle with the drug molecules attached conjugates with several antibody molecules and aggregates to form a larger particle, which will scatter transmitted light, and as the reaction proceeds, the abundance will increase. If drug molecules are present in the sample, they will compete with the conjugates bound to antibodies and result in a decrease in the rate of absorbance increase in proportion to the concentration of drug present.

Sample Extraction

There are two major methods for sample extraction:

Solvent Extraction (Liquid–Liquid Extraction)

This is the most frequently used separation technique in toxicology laboratories worldwide. Most drugs have some degree of polarity and so it is important to select a solvent that will maximize the extraction of the target drugs but minimize the extraction of endogenous compounds. By adjusting the pH of the specimen, drugs can be separated into basic and acidic drugs.

Making the specimen basic (pH 9) by the addition of ammonia or sodium borate buffer will favor the extraction of weakly basic drugs. Buffering the specimen to pH 4 by the addition of an acidic buffer (potassium dihydrogen phosphate) will allow the extraction of acidic and neutral drugs. Basic drugs comprise the majority of drugs found in forensic cases and are often present at low concentrations in blood. To improve the detection of these drugs, it may be necessary to incorporate a cleanup step (or back extraction) in the extraction scheme to remove more of the endogenous compounds and still retain the drugs of interest. This can be particularly important when analyzing postmortem blood specimens that can often contain a multitude of endogenous compounds formed postmortem. Once the specimen has been extracted at basic pH into an appropriate solvent (such as butyl chloride), it is back extracted into aqueous acid solution (usually 0.1 M sulfuric acid), and the acidic and neutral compounds will remain in the organic layer. The acidic layer is separated from the organic layer and is then made alkaline (sodium hydroxide) and reextracted into organic solvent, which is then separated from the aqueous and concentrated, usually under a stream of nitrogen. Care should be exercised in the evaporation step as some of the more volatile compounds can be lost if subjected to heat; amphetamine and methylamphetamine are prime examples.

The concentrated extract can now be analyzed using the appropriate chromatographic technique. A typical basic/neutral drug extraction scheme is shown in Figure 4.

Acidic drugs of forensic interest tend to be present in much higher concentrations than basic drugs and the need for a cleanup step in the extraction is generally not required. If a cleanup step is required, it can be achieved by the partitioning

between immiscible solvents of differing polarities. The more lipid-soluble endogenous compounds (sterols and fatty acids) will partition into the less-polar solvent (e.g., petroleum ether), whereas the more polar drugs will partition into the more polar solvent (e.g., acetonitrile). A typical extraction scheme for acidic and neutral drugs is shown in Figure 5.

Figure 4 Extraction scheme for basic and neutral drugs.

Figure 5 Extraction scheme for acidic/neutral drugs.

Solid-Phase Extraction

Solid-phase extraction (SPE) techniques have become more common in forensic toxicology laboratories because of their better extraction efficiencies, particularly with more polar drugs, and the ability to automate the extraction using liquid handling systems. Initial difficulties with postmortem samples, which often contain large amounts of particulate material, are often clotted, and in the past could easily plug the fine SPE absorbent packing, have now been overcome by better sample preparation techniques (sample dilution and centrifugation) and improved SPE column technology.

There are predominantly three different mechanisms for the retention of compounds, which are retained by the sorbent:

1. Reverse phase – Polar liquid phase and nonpolar solid phase. Compounds are retained by hydrophobic interactions (nonpolar–nonpolar interactions, dispersion forces).
2. Normal phase – Nonpolar liquid phase and polar solid phase. Compounds are retained by hydrophilic interactions (polar–polar interactions, hydrogen bonding).
3. Ion exchange – Electrostatic attraction of charged group on the compound and charged group on the sorbent.

Table 2 shows the characteristics of solvents commonly used in SPE.

The basic procedure for SPE is a five-step process as shown in **Figure 6**, and a typical SPE using a combination of a strong cation exchange and a C8 sorbent for the analysis of opiates in blood is shown in **Figure 7**.

Solid-Phase Microextraction

An alternative technique to liquid–liquid extraction and SPE is the solid-phase microextraction (SPME). It has been developed for the analysis of volatile and some nonvolatile compounds. This technique incorporates sample extraction, concentration, and sample introduction in one step and is fast, requires no solvents, is reusable, and can be adapted to any GC. It consists of a fused silica fiber coated with a stationary phase that is attached to a stainless steel plunger. After inserting the plunger through a septum into a vial containing the sample, the fiber is

exposed to either the headspace or the liquid for 20–30 min. The equilibration time can be reduced by increasing the ionic strength of the sample, stirring, or heating the sample. After equilibration, the fiber is retracted back into the plunger and inserted into the GC injection port where it is desorbed by exposing the fiber again (see **Figure 8**).

This also serves to recondition the fiber, which can be reused for up to 100 further analyses. The fiber may also be reextracted into an organic solvent and analyzed by liquid chromatography (LC). There are a number of different stationary phases available to suit the type of analysis.

Screening by GC

GC has been one of the most widely used techniques in forensic toxicology laboratories. If a drug has sufficient volatility for it to exist in the vapor phase at temperatures up to 350 °C without decomposing, then there is a high probability that it can be analyzed by GC. Sample extracts can be separated into their components by introducing an aliquot of the extract (sample injection) onto a column that contains a stationary phase that has a continuous flow of an inert gas (e.g., helium) through it. This column is contained in an oven with controlled temperature. The components within the extraction mixture will spend differing periods of time in the stationary phase depending upon their affinity for it and the time for the molecules to reach the end of the column will vary (retention time). For molecules that have a greater affinity, the time will be longer as they will spend longer time immobilized in the stationary phase compared with those that have a lesser affinity. As the components elute from the end of the column, there will be a detector that will produce a signal that is proportional to the amount of the compound present, the signal is then processed and recorded. Each compound that elutes from the column will have a characteristic retention time, which can be defined as the time interval between sample injection and detector response.

Few solid stationary phases are used for screening in forensic toxicology, however, many forensic laboratories analyze blood and other liquid biological specimens for alcohol concentration using either graphitized carbon black or polymer conventional packed columns, which are extremely good at

Table 2 Characteristics of commonly used solvents in SPE

		Strong			Polar

Figure 9 Blood alcohol analysis – sample preparation for direct injection technique.

A typical chromatogram of ethanol analysis using a $2\text{ m} \times 2\text{ mm}$ internal diameter (i.d.) glass column packed with Carbowax C with 0.2% Carbowax 20 M is shown in [Figure 11](#).

There are a number of different liquid stationary phases that can be utilized depending on the nature of the compounds that

require separation with the most common comprising polysiloxanes. These stationary phases are liquids coated to the inside of a fused silica capillary column. Dimensions of the capillary column can vary between 0.1 and 0.32 mm i.d. and can be from 10 to 60 m in length.

Figure 10 Blood alcohol analysis: headspace technique.

Figure 11 Chromatogram of ethanol analysis in blood: 2 m × 2 mm i.d. glass column packed with Carbowax C with 0.2% Carbowax 20 M. Oven 100 °C, injection port 220 °C, FID 220 °C, He carrier gas flow 30 ml min⁻¹.

Headspace analysis

The headspace sampling technique can be used to screen biological samples for the presence of volatile hydrocarbons (e.g., petroleum products, propane, and butane). To increase the sensitivity of this technique, it is usual to sample a large volume of headspace (50 ml) and pass it through an adsorbent (e.g., Porapak Q) to trap the volatiles, which is then thermally desorbed onto a GC column. For complex mixtures, it is usual to

analyze the headspace by capillary GC/MS. **Figure 12** shows a typical total ion trace for a headspace sample of petrol in blood.

Detectors

Some detectors, for example, flame ionization detectors (FID), are nonspecific in nature and will respond to almost all compounds that pass through the GC column while there are others that will specifically respond to compounds that contain particular atoms. For example, the NPDs will detect compounds that contain nitrogen or phosphorus and EPDs will detect compounds that have electron-capturing atoms or functional groups (e.g., halogens, nitro groups, and carbonyl groups). The NPD is extremely useful in drug screening because most drugs contain nitrogen and solvents and many of the endogenous compounds in biological samples that are coextracted (e.g., fatty acids, lipids, and sterols) do not. There are a number of relative retention databases using standard capillary columns available for compound identification. The ECD is a highly sensitive selective detector particularly useful to detect benzodiazepines and halogenated pesticides and herbicides. These detectors also offer greater sensitivity and selectivity over nonspecific detectors. This greater sensitivity can be utilized by derivatizing the compounds with functional groups containing halogen, for example, trifluoroacetic, pentafluoropropionic, and heptafluorobutyric anhydrides.

MS detectors have become increasingly popular as they provide the opportunity for unique identification of compounds. The most commonly used MS detector uses an electron impact technique to ionize the compounds eluting from the capillary column, which then fragments in a characteristic and reproducible way. These fragments are focused and accelerated into a mass filter (quadrupole or ion trap), which rapidly scans for masses, usually in the range up to about 1000 amu. The characteristic mass spectrum produced can be searched against a number of commercial mass spectral libraries (e.g., PMW (Pfleger, Maurer, Weber), MPW (Maurer, Pfeleger, Weber), NIST, and Wiley libraries) as well as in-house user-generated libraries. The advances in computer technology allow the searching of vast library data extremely fast.

For added sensitivity, the quadrupole MS can be operated in the selected ion mode (SIM) where only preselected masses for the compounds of interest are collected. This is a useful technique for targeted screening of drugs but is limited for general unknown screening.

The ion trap detector offers similar sensitivity when operated in either the full scan or the SIM mode due to its longer ion collection period. Mass spectra produced by the two different mass detectors are sometimes quite different as they are characterized by the conditions under which they are run, and this can make comparison between different instruments difficult.

Dual detector systems

It is not uncommon in forensic toxicology laboratories to use a dual detector screening system. There are several different combinations that can be used, and the sample can be split at the injection port and two columns of differing polarity used to separate the drugs in the extract (**Figure 13**) or the effluent from the column can be split between two different detectors (**Figure 14**).

Figure 12 Total ion chromatogram of a headspace sample containing petrol: 60 m $\times$ 0.25 mm i.d. BP-1 capillary (film thickness 1 μ m), oven temperature 45 $^{\circ}$ C (6 min) to 260 $^{\circ}$ C at 10 $^{\circ}$ C min $^{-1}$.

Figure 13 Sample injection split between two different columns.

Figure 14 Column effluent split between two detectors.

When using the single-injection dual column approach, the effluent from both columns will be detected by the same type of detector (usually NPD or ECD) and a relative retention time (RRT) data base can be set up for both columns (e.g., DB-1 and DB-17). Searching the RRT of unknown peaks in the two chromatograms will provide better discrimination as to the identity of the unknown than if data from a single chromatogram was used (Figure 15). A much more common configuration is to split the effluent from the end of the column to two detectors, one being an NPD and the other, an MSD. By using the NPD chromatogram to identify peaks of interest (many endogenous peaks will not produce an NPD response), the mass spectrum of the peak at the corresponding retention time can be obtained from the MS total ion chromatogram (TIC) (Figure 16).

Gas Chromatography–Mass Spectrometry

The use of gas chromatography–mass spectrometry (GC–MS) to screen biological samples for drugs is also a popular

technique. However, because extracts from biological samples often contain many endogenous compounds, the technique requires an extensive sample preparation before GC–MS analysis if a general drug screen is required. TIC-containing endogenous compounds can often mask low concentrations of drugs. An alternative technique is to use selected ion extraction for characteristic ions of drugs of interest, and these extracted ion chromatograms can show the presence of drugs even if the TIC does not. Unfortunately, this technique can limit the number of drugs that can be screened for but is very good for selective drug screening. Figure 17 shows a TIC and extracted ion chromatogram of a blood extract.

Screening by Liquid Chromatography

HPLC with Photodiodearray Detector

At one time, HPLC was only used for the analysis of compounds that could not be analyzed by GC (nonvolatile thermally unstable compounds). Since the introduction of the

Figure 15 Dual column NPD chromatogram. Column oven 100 °C (0.5 min)–280 °C (8 min) at 10 °C min⁻¹, injection port 250 °C, detector 325 °C, He carrier 4.9 ml min⁻¹, splitless injection.

photodiode array detector (DAD) in the mid-1980s, the ability to produce a UV spectrum has dramatically increased the use of HPLC systems for routine drug screening. The identification of drugs is based on the combination of retention time and UV spectrum as shown in Figure 18.

LC is the separation of components in a mixture based on the selective partitioning of compounds between a liquid mobile phase and a stationary phase. The sample is introduced through an injection port into the mobile phase stream, delivered by the high-pressure pump, and moves through the column where the separation takes place. They are then detected at the column outlet with a flow through detector or are transferred into a MS.

The selection of the stationary phase and mobile phase is important as alterations to one or the other can lead to improved compound separation particularly when there are endogenous compounds present.

LC-MS and Liquid Chromatography-Tandem Mass Spectrometry

Over the last decade, the use of LC-MS and liquid chromatography-tandem mass spectrometry (LC-MS/MS) has become increasingly important in drug screening because of the high selectivity of MS detection and the possibility of analyzing aqueous samples and polar, thermally labile and nonvolatile analytes. The application of single-stage quadrupole or ion trap mass spectrometers for screening is limited due to coeluting compounds and high matrix burden. Methods for STA using

triple-stage quadrupole or hybrid triple-quadrupole linear ion trap mass spectrometers have solved these problems. Instruments have been greatly improved and a new screening technique based on high-resolution MS with benchtop time-of-flight (TOF) has been recently developed.

Recent developments of LC-MS-based screening procedures have covered hundreds of toxicologically important compounds and can be divided into three general approaches.

Multitargeted Screening

This method uses triple-stage quadrupole or hybrid triple-quadrupole linear ion trap mass spectrometers and relies on the mass spectral information of the analytes of interest being included in the method. The number of compounds that can be included is limited by the minimum dwell time for each multireaction monitoring (MRM) transition included in the one measurement cycle. This was a limitation to the number of compounds that could be screened for; however, software development has allowed for the scheduling of MRM's within-time windows for transitions monitored by the survey scan allowing the overall number of transitions in a method to be increased dramatically.

Ion Trap or Triple-Quadrupole Mass Spectrometers

These techniques generate information-rich product ion spectra, which, like with GC/MS, can then be searched against reference mass spectral libraries. One drawback of this

Figure 16 Dual detector (MSD and NPD). Column: 30 m $\times$ 0.25 mm i.d. HP-5: 60 $^{\circ}$ C (2 min)–300 $^{\circ}$ C at 20 $^{\circ}$ C min $^{-1}$, He carrier 4 ml min $^{-1}$, injection port 280 $^{\circ}$ C, NPD 280 $^{\circ}$ C, MSD transfer line 260 $^{\circ}$ C.

technique is that the reference libraries need to have had their mass spectra generated on the same or very similar instrumentation. Using MRM, information dependent acquisition (IDA), and enhanced product ion (EPI) scanning, an electrospray ionization (ESI)–MS/MS library containing 1253 drugs, pharmaceuticals, and toxic organic compounds of forensic and clinical significance has been generated. This approach can be used for both targeted and untargeted screening.

High-Resolution Accurate Mass Spectrometers

This technique is inherently untargeted and is based on accurate mass measurements with benchtop TOF mass spectrometers. Compounds are identified by comparison of the accurate mass measured in the sample with accurate mass databases of toxicological relevant compounds. With this approach, accurate mass and isotopic patterns alone do not give sufficient information for unequivocal identification and more structural-specific

Table 3 Precursor ions and major product ions for each of the amphetamines in Figure 19

ID	Q1 Mass	Qualifier masses	RT (min)
Amphetamine	136	119, 91, 65	4.0
Paramethoxyamphetamine (PMA)	166	149, 121, 91	6.1
Ephedrine	166	148, 133, 117	2.7
Pseudoephedrine	166	148, 133, 117	3.2
Methylenedioxyamphetamine (MDA)	180	163, 105, 133	5.6
Methylenedioxyethamphetamine (MDEA)	208	163, 133, 105	7.1
Methylenedioxymethamphetamine (MDMA)	194	163, 133, 105	6.2
Methamphetamine	150	119, 91, 65	5.1
Phenylephrine	168	150, 109, 91	1.1
Phentermine	150	91, 133, 105	6.1
Mephentermine	164	91, 133, 105	6.7
D5-MDMA	199	165	6.1
D5-Methamphetamine	155	121	5.0
D5-Amphetamine	141	93	4.0

information can be obtained from collision-induced dissociation (CID) fragment spectra using in-source CID. Hybrid quadrupole time-of-flight mass spectrometry (LC-QTOF-MS) provides the advantage of fragment spectra not affected by matrix and coeluting compounds. When operated in a data-dependent acquisition mode (auto MS/MS) where the presence of a nominated ion triggers an MS/MS of the compound, it combines the advantage of TOF-MS for comprehensive data collection with the measurement of accurate CID fragment spectra from all relevant compounds.

Mass Spectrometer Inlet Systems

There are two main interfaces that allow the introduction of a liquid effluent from the LC column at atmospheric pressure into the high-vacuum mass spectrometer system: ESI and atmospheric pressure chemical ionization (APCI). In ESI, the column effluent is formed into charged droplets using a strong electrical field with ions produced from evaporating solution droplets. In APCI, the effluent is first nebulized and then heated with ions produced by gas-phase ion–molecule reactions. A series of low-pressure chambers and ion-focusing lenses is used to optimally transport the ions into the MS. Both ESI and APCI produce limited spectral information compared to electron impact mass spectra and for identification purposes, it is often necessary to perform secondary fragmentation (MS/MS). Figure 19 shows the separation of amphetamines in blood using LC-ESI/MS/MS. Table 3 shows the selected precursor ions $[M+H]^+$ and the resultant fragment ions used for the identification of the compounds.

One problem that is commonly encountered in LC-MS is ion suppression. Matrix effects can either reduce the response of the compound of interest (ion suppression) or increase it (ion enhancement). Both can seriously compromise the accuracy of quantitation and in a worst case scenario, ion suppression could lead to false negative result. For this reason, experiments on matrix effects are an essential part of LC-MS (MS)-based method validation, sample preparation should reduce the amount of endogenous compounds in the matrix extract that can lead to ion suppression, and the effect of other compounds used in the analysis (salts, drugs, metabolites, and

deuterated internal standards) should be evaluated before using this technique routinely.

Methods of Analysis – Confirmatory Testing

A Poletti, University of Verona, Verona, Italy

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Confirmatory test An analytical test capable of identifying a xenobiotic, presumptively detected in a sample by a first-level (screening) test.

Measurement uncertainty Measurement of the cumulative effect of all possible sources of variability resulting from the application of a given analytical method.

Method validation Set of tests carried out in order to assess the ability of an analytical method to achieve the objectives it has been developed for. They typically include evaluation of specificity, lower limit of detection and of

quantification (LLOQ), upper limit of quantification (ULOQ), absolute recovery, matrix effect, calibration range, accuracy and precision within the same analytical session and between different sessions (at LLOQ and at least another level), analyte stability, robustness, and applicability of dilution.

Minimum required identification criteria Criteria that must be met at least in order to properly identify a compound in a sample. They may be specific of the analytical technique or set of analytical techniques adopted, and must be established in advance.

Abbreviations

GC	Gas chromatography
HRMS	High-resolution mass spectrometry
IP	Identification points
IS	Internal standard
ISO	International Organization for Standardization
LC	Liquid chromatography
LLOQ	Lower limit of quantification
LRMS	Low-resolution mass spectrometry
MDA	3,4-Methylenedioxyamphetamine
MDEA	3,4-Methylenedioxyethylamphetamine

MDMA	3,4-Methylenedioxymethylamphetamine
MRIC	Minimum required identification criteria
MRQC	Minimum required quantification criteria
MS	Mass spectrometry
RRT	Relative retention time
RT	Retention time
SI	International System of Units
SIM	Selected ion monitoring
SRM	Selected reaction monitoring
ULOQ	Upper limit of quantification

Principles of Confirmatory Testing

In a forensic setting, truth must be established beyond any reasonable doubt in order to guarantee the rights of all parties. This obvious but nevertheless essential principle, when transferred to analytical toxicology, requires unequivocal identification of a xenobiotic in a sample. The identification of a drug (most commonly a xenobiotic) in a sample is quite often a critical step in a forensic investigation, proving the link between drug use and a judicially relevant event. These events could be drug dealing, driving under influence, a workplace accident, a drug-facilitated sexual assault, or even a homicide.

In forensic toxicology, it is generally accepted that identification must be accomplished through the use of at least two analytical techniques based on different chemical and physical principles, supporting the results of each other. Therefore, whenever a presumptive identification is obtained, a second confirmatory test must be applied producing an analytical result as independent as possible from that of the first-level (screening) test. The rationale behind this principle is that the chance that both tests (screening and confirmatory) may give a false positive identification must be as low as possible. Therefore, a confirmatory method based on a detection principle very similar to that of the

screening test is unacceptable (e.g., confirmation of an immunochemical result with another immunochemical method). The use of a chromatographic technique to confirm a result obtained by chromatography is acceptable only if the two separation techniques produce different results (i.e., significantly different retention behavior for the same analyte). The introduction of hyphenated chromatographic and spectroscopic techniques (e.g., liquid chromatography (LC) combined with ultraviolet-visible spectrophotometry or gas chromatography (GC)/LC combined to mass spectrometry (MS)) has somewhat changed this picture, as these involve the application of two different analytical techniques within a single test. While the use of hyphenated chromatographic and spectroscopic techniques for confirmatory purposes is correct in principle, it must be clear that it is viable only if it does exclude the possibility of a false positive result due to contamination during sample processing and/or instrumental analysis (i.e., by including the analysis of reagent blanks and sample blanks within the batch of samples).

The confirmatory test must be characterized by a higher analytical selectivity, and therefore better specificity (expressed as the ratio of true negatives/(true negatives + false positives)) and at least equal, but preferably better, sensitivity (true positives/(true positives + false negatives)) than the first-level (screening) test.

Quite often, the screening test does not discriminate between related substances (either parent compound and metabolites, e.g., heroin and its phase I and phase II metabolites, or a group of structurally related compounds, e.g., ecstasy and derivatives), whereas the confirmatory test enables the specific detection and identification of each single compound/metabolite. Therefore, the sensitivity of the screening method is often referred to the drug class (e.g., opiates, ecstasy, and derivatives), while that of the confirmatory test is referred to each single compound/metabolite (morphine, 6-acetylmorphine, codeine, or 3,4-methylenedioxymethylamphetamine, 3,4-methylenedioxyamphetamine, 3,4-methylenedioxyethylamphetamine, etc.). In such a case, by definition, the sensitivity of the confirmatory test must be better than that of the screening test (as a rule of thumb, the cutoff for a compound in the confirmatory test should be at least one half of the cutoff for the drug class in the screening test).

Whenever a large number of samples needs to be tested for forensic purposes (e.g., in workplace drug testing), the application of the confirmatory testing responds also to cost-efficiency reasons. It is economically efficient to perform a rapid, automated and low-cost screening test (e.g., a colorimetric, enzymatic, or immunochemical test) providing adequate sensitivity (i.e., low rate of false negatives) and submit all presumptive positive results to confirmation, which typically requires more expensive, complex, and time-consuming tests.

Analytical procedures used in confirmatory testing must not only be standardized and available in written form, but also be fully validated according to an internationally accepted standard. The laboratory should be also accredited according to the International Organization for Standardization (ISO) 17025 requirements. In addition, they must provide all the necessary details, specifications, and criteria for the execution, verification, and interpretation of results. A parameter deserving particular attention in the validation of a confirmatory testing is analytical selectivity. This is typically verified either through the separate analysis of different blank samples ($n = 6-10$) and through the analysis of samples containing the most frequently encountered exogenous compounds within the geographical area or the particular setting of the samples to be confirmed. In both cases, the absence of any interference to the target analyte's detection must be proved.

Although it is beyond the scope of the present article, it must be realized that, in order to establish a link between the use of a drug or poison and a crime, not only a proper analytical strategy – including an adequate confirmatory testing – must be implemented, but also, and equally importantly, a proper chain of custody ensuring the authenticity, integrity, and traceability of the sample needs to be ensured. In addition, if not already established by specific regulations, it is advisable, whenever possible, to collect a further sample aliquot (sample B or revision sample) identical to that used for screening and confirmatory purposes (sample A) that must be properly stored in a sealed container and kept available for further testing (counter or revision analysis) in case of disputes on the results obtained on sample A.

Certified Reference Standards

Proper identification of an analyte for forensic purposes requires that, whenever feasible, the reference standard be

examined under identical analytical conditions of the unknown, providing results that fulfill all the required identification criteria discussed later in this article. Therefore, whenever a reference standard of certified purity (within the expiry date) may be obtained, definitive identification must be achieved by direct comparison with the reference standard. If a certified reference standard is not available, another standard may be used. In cases when neither is available, reference analytical data (e.g., reference relative retention time (RRT) or retention index or reference mass spectrum contained in a database) may be used provided that their origin and quality are verified and that the instrumental conditions used to obtain them match those used for the analysis of the unknown.

MS in Confirmatory Testing

The application of MS in confirmatory testing, owing to the intrinsic analytical selectivity of this technique (MS provides an absolute measure of the mass/charge ratio of the molecular or pseudomolecular ion and of specific fragment ions). It is generally accepted that, whenever its application is feasible, MS is the technique of choice for confirmation purposes. However, recent developments in MS have led to a spread of MS-based analytical techniques, including single, tandem MS (MS-MS) and multiple configurations (MSⁿ), at low-resolution MS or high-resolution MS (HRMS) mass resolution, alone or in combination with one or more chromatographic separation techniques (e.g., GC, LC, coupled column LC, and LC-LC). As a result, minimum required identification criteria (MRIC) for each of these techniques and their combinations have still to be determined (see the section '[Minimum Required Identification Criteria](#)').

Internal Standardization

In all cases where the instrumental technique makes it feasible and appropriate, it is strongly advisable to use an internal standard (IS) in confirmatory testing. The addition of one or more (ISs) increases the certainty of identification and quantification. The IS provides higher precision and accuracy to the measurement of chromatographic retention (RRT = analyte retention time/IS retention time) of the analyte and to its quantification as well (by correcting for volume errors, variability in extraction efficiency, and instability of the detection system). Alternatively, other more complex means of standardization of chromatographic retention may be adopted (e.g., Kovats retention indices). The IS must be added to samples and controls as early as possible during the sample preparation procedure, that is, before any treatment of the sample. Hair – and other solid and nonhomogeneous substrates – represent an exception to this rule as the added IS might be removed during sample treatment (e.g., washing) preceding extraction. Therefore, it is advisable to add the IS after washing, cutting/powdering, and weighing of the hair sample. Whenever an MS technique is involved, the use of deuterated or other isotope-labeled ISs (with a mass difference ≥ 3 from the unlabeled analyte) should be considered as their behavior, in terms of chromatographic retention and MS fragmentation, is *nearly*

identical to that of the corresponding unlabeled analyte, yet it allows the MS differentiation from the unlabeled analyte. The use of other unlabeled compounds as IS is a viable alternative when an isotope-labeled IS is not available, provided that the presence of the compound in the sample has been excluded, and its MS separation from the target analyte is ensured, particularly in the case of (even partial) coelution with the target analyte.

When LC–MS is adopted as the instrumental technique, it is advisable to adjust chromatographic conditions in order to make the target analyte and the IS to elute as close as possible to each other in order to account for matrix effects phenomena (e.g., ion suppression). The amount of isotope-labeled standard added to samples should be properly selected in order to avoid any significant effect on ionization efficiency (e.g., due to competition for ionization) or quantification (e.g., due to isotopic contributions) of the analyte. The stability of the IS during sample preparation and storage in the autosampler must be verified during the method validation.

Minimum Required Identification Criteria

For any analytical techniques or combinations applied to confirmatory testing, MRIC can be established and adopted following the directions and suggestions of relevant regulations, guidelines of scientific associations, reference literature, and general principles accepted by the scientific community. These criteria must be properly assessed in order to achieve the identification of an analyte in a sample.

Table 1 shows typical MRIC adopted for the most common analytical techniques.

For gas chromatographic analysis, the absolute retention time (RT) or the RRT to an IS should be within $\pm 1\%$ and $\pm 2\%$, respectively, of that obtained for the standard analyte

in the positive control for capillary GC. For LC, a wider tolerance window is acceptable ($\pm 2\%$ and $\pm 4\%$ for RT and RRT, respectively).

When full scan MS analysis is adopted, a preliminary identification may be achieved by comparing the MS spectrum of the unknown and that of the reference analyte using one of the available MS library search algorithms. To this purpose, as mass spectra obtained from biological extracts are sometimes affected by chemical noise, it is strongly advised to adopt reverse-search algorithms instead of forward-search ones. Reverse-search algorithms look for the presence of fragment ions of the reference mass spectrum in the unknown mass spectrum, whereas forward-search algorithms do the opposite. Therefore, the presence of any interference fragment ions in the unknown mass spectrum will not affect the matching result of the reverse-search as they do when a forward-search algorithm is applied. Owing to the ability of reverse-search algorithms to identify mass spectra in the presence of chemical noise, at least to some extent, it is also recommended to avoid background subtraction of the unknown mass spectrum, in order to prevent any distortion of relative mass abundances of the fragment ions specific to the unknown analyte, thus affecting the matching result.

Another essential requisite of confirmatory testing by full scan MS is the appropriate selection of the scan range. The upper limit of the acquisition range should be at least 30 mass units higher than the mass of the reference compound, in order to account for the formation of possible adducts, and the lower limit should equal that used for the acquisition of mass spectra of the reference database (typically m/z 50). However, it must be noted that for some compounds, for example, amphetamine-like drugs and tricyclic antidepressants, the lower limit should be reduced to m/z 30 or 40 in order to include the base mass peak ($[\text{CH}_4\text{N}]^+$, m/z 30; $[\text{C}_2\text{H}_6\text{N}]^+$, m/z 44) and to increase selectivity of detection as well. After preliminary identification by library search, proper

Table 1 Typical minimum required identification criteria adopted for the most widespread analytical techniques

Analytical technique	Minimum required identification criteria
Capillary gas chromatography	Absolute RT of the unknown within $\pm 2\%$ (or RRT within $\pm 1\%$) of the reference analyte
Liquid chromatography	Absolute RT of the unknown within $\pm 4\%$ (or RRT of within $\pm 2\%$) of the reference analyte
MS analysis in full scan mode	(1) All fragment ions of the reference spectrum with a relative abundance higher than 10% of the base peak must be present in the unknown, not background-subtracted, mass spectrum (2) The relative abundance of these ions in the unknown spectrum must be within $\pm 20\%$ of that of the corresponding ions in the reference analyte spectrum
MS analysis in selected ion monitoring (SIM) mode	(1) At least three fragment ions (2) Ion ratios for the unknown spectrum within $\pm 20\%$ of those of the reference analyte (if fragment ions with $\leq 10\%$ relative abundance in the full scan spectrum of the reference analyte are selected, a $\pm 50\%$ tolerance is acceptable)
MS/MS analysis in product ion full scan mode	(1) All fragment ions of the reference product ion spectrum with a relative abundance higher than 10% must be present in the unknown, not background subtracted, product ion mass spectrum (2) The relative abundance of these ions in the unknown spectrum must be within $\pm 20\%$ of that of the corresponding ions in the reference analyte spectrum (3) The surviving precursor ion should be present in the product ion spectrum with a relative abundance $\geq 5\%$
MS/MS analysis in selected reaction monitoring (SRM) mode	(1) At least two precursor-to-product transitions (2) The relative abundance of the two product ions must be within $\pm 25\%$ of the corresponding value obtained for the reference analyte

RT, absolute retention time; RRT, retention time relative to an internal standard.

identification should be accomplished by verifying that all criteria listed in **Table 1** for identification in MS full scan mode are fulfilled.

Whenever the confirmation of a target analyte must be achieved, MS analysis in selected ion monitoring (SIM) mode may be adopted instead of full scan. In such a case, at least three fragment ions per compound should be monitored. These should include the molecular ion or adduct, depending on the ionization technique used, and exclude isotopic peaks and nonspecific losses (e.g., loss of water). The ratios between fragment ion peaks (heights or, preferably, areas) should be within $\pm 20\%$ of those obtained for the analyte in the positive control. However, for fragment ions whose relative abundance is lower than 10% in the full scan reference spectrum, a $\pm 50\%$ tolerance may be accepted.

For tandem MS analysis (MS–MS) of product ions in full scan mode (i.e., product ion scan), the same criteria described for full scan single MS analysis apply. In addition, the molecular or pseudomolecular ion should be selected as precursor ion, and the product ion spectrum should include the surviving precursor ion with a relative abundance of at least 5%.

Confirmatory analysis in MS–MS selected reaction monitoring (SRM) mode should be performed by monitoring at least two precursor-to-product transitions. The precursor ions of the transitions monitored should be either the molecular/pseudomolecular ion, or an adduct (depending on the ionization technique applied), or another structurally specific ion, and the product ions should not result from nonspecific losses (e.g., loss of water). In addition, the ratio of the two product ion peaks (heights or, preferably, areas) should be within $\pm 25\%$ of the corresponding value obtained for the positive control.

Exceptions to these MRICs may be adopted only if they are justified by the physical–chemical and/or structural characteristics of the analyte, or by the limitations in the instrumental technique used. Reasons justifying any deviations from the MRIC discussed earlier must be reported in the corresponding standardized operating procedure of the confirmatory test.

Alternatively, in order to avoid deviations from MRIC, a modification in the chromatographic behavior and/or in the fragmentation pattern of an analyte may be obtained by means of derivatization techniques. In addition, as a general rule, the identification of specific metabolic products or precursors of an analyte in the sample may be used in order to further support the identification of the analyte.

If analytical techniques or combinations other than those listed earlier are used, no generally accepted MRIC are usually available. However, a general validity procedure for setting specific identification criteria may be adopted, such as the so-called ad hoc confirmation package widely used in the veterinary area. This procedure is based on the principle that any analytical technique possesses a certain discrimination power of its own. Therefore, a definite number of identification points (IP) may be attributed to each analytical technique. IP resulting from the application of different techniques in either an online or offline combination may be summed up, the total number of IP corresponding to the sum of each IP contribution derived from each individual technique. An example of this approach is the IP system established by the European Commission Decision 2002/657/EC (12 August 2002)

Table 2 Number of identification points (IP) relative to different combinations of MS ions acquired with different instrumental techniques

<i>Analytical technique</i>	<i>Number of ions monitored</i>	<i>IP</i>
Low-resolution MS (LRMS)	<i>N</i>	<i>N</i>
LC/LRMS or GC/LRMS	<i>N</i>	<i>N</i> + 1
LRMS ^a (precursor ion)	1	1
LRMS ^a (product ion ^a)	<i>N</i>	1.5 <i>N</i>
High-resolution MS (HRMS)	<i>N</i>	2 <i>N</i>
HRMS ^a (precursor ion)	1	2
HRMS ^a (product ion ^a)	<i>N</i>	2.5 <i>N</i>

^aThe same number of IP applies to MS³ or higher ions.

implementing Council Directive 96/23/EC concerning the performance of analytical methods and interpretation of results. According to this system, the identification of an unknown compound is achieved with sufficient selectivity when, through the application of an analytical technique or more analytical techniques in either online or offline combination, a total of at least 4 IP is reached. **Table 2** shows some examples of the total number of IP relative to different combinations of MS ions acquired with different instrumental techniques. For example, a chromatographic/mass spectrometric analysis in SIM mode with three ions monitored would provide a total of 4 IP: 1 IP from chromatographic separation and one for each of the ions monitored, provided that the MRIC described in **Table 1** for the corresponding techniques are all met. A tandem mass spectrometric analysis where two transitions from the same precursor ion are monitored would also provide a total of 4 IPs: 1 IP from the monitoring of the precursor ion, and 1.5 IP for each of the two product ions (again, MRIC for tandem MS analysis in SRM described in **Table 1** need to be met). If a chromatographic separation is placed before MS–MS analysis, the total number of IP rises up to 5. The use of HRMS allows a considerable gain in the number of IP per ion, owing to the much higher selectivity of the technique (see **Table 2**).

Minimum Required Quantification Criteria

Frequently, a confirmatory test may be used also for quantification purposes. Therefore, in addition to minimum identification criteria, minimum required quantification criteria (MRQC) should also be adopted and satisfied. If the method is used for qualitative confirmation purposes with reference to a predetermined cutoff, the measurement uncertainty in correspondence to this value must be evaluated and subtracted from the measured value; a positive result shall be reported only in case the measured value, subtracted from the measurement uncertainty, falls above the confirmation cutoff. The result of a qualitative confirmatory test should be reported exclusively as a positive/negative or inconclusive result, the latter applying to cases where any of the batch or sample validation criteria are not met.

Whenever a confirmatory method is used for quantification purposes, its quantification performance must be thoroughly validated through the assessment of the overall measurement uncertainty, the lower limit of quantification, the upper limit of quantification (ULOQ), and the calibration range. The applicability of dilution to samples with an expected analyte's concentration falling above the ULOQ should also be validated. The quantification procedure shall include, among the MRQC, the quantification of an adequate number of negative and positive quality controls within a predefined tolerance. The result of a quantitative analysis must be expressed in a uniform measurement unit, preferably accepted by the International System of Units, avoiding any doubtful interpretation, and directly comparable to the measurement unit of reference values, if available.

Postmortem Specimens

GR Jones, Alberta Medical Examiners Office, Edmonton, AB, Canada

© 2013 Elsevier Ltd. All rights reserved.

Introduction

In theory, modern analytical techniques allow most drugs and poisons to be measured in almost any biological fluid or tissue. However, the practical choice of which human fluids or tissues to use comes down to two main factors – what is available and the interpretive value of the results. For a body that has been outside for weeks or months, bone, and possibly bone marrow, may be all that is available as the remainder of the body has decomposed and may also have been devoured by insects and scavengers. In order to interpret the results, there must be a body of knowledge that allows sense to be made of drug concentrations. This applies to both drugs (prescribed or illicit) taken by humans or substances they may be exposed to (e.g., pesticides). For reasons largely beyond the scope of this section, reliance on a single measurement of a drug in a single specimen is best avoided because of a possible overlap of so-called therapeutic and toxic ranges. Measurement of drug concentrations in more than one specimen type can increase the reliability of interpretation. The following section outlines some of the advantages and disadvantages of various specimens for postmortem toxicology.

Blood, Serum, and Plasma

The term 'blood' usually refers to whole blood as it would be drawn from a vein or artery. If the red and white cells are spun down by centrifugation, the clear straw-colored fluid on top is plasma. If whole blood is allowed to clot and the clot separated by centrifugation, the clear straw-colored fluid is called serum. For forensic toxicology purposes, plasma and serum are usually regarded as equivalent.

With some exceptions, blood is regarded as the primary specimen for forensic toxicology. During life, blood is a living fluid that circulates to, and is in equilibrium with, virtually all tissues, including the receptors where many drugs have their site of action. However, after death, blood cells die and the cells lyse, the red cells releasing large amounts of hemoglobin. Therefore, most postmortem toxicology testing relies not on serum or plasma (as for most clinical toxicology testing), but on whole, hemolyzed blood. Despite the processes that occur after death, postmortem blood is typically a dark red fluid containing numerous microclots, which, with some care, may be measured by pipette. After the blood circulation ceases, sedimentation occurs, where the red blood cells gradually settle to the lowest point in an organ or tissue. Therefore, the hemoglobin concentration of any given blood sample can vary considerably, depending on where it was drawn from. Where the difference in drug concentration between red cells and plasma is more or less even, sedimentation should not have a significant effect on interpretation. However, where the concentration of a drug is significantly different in red cells versus plasma, interpretation may be markedly affected.

Collection Site

Blood is most conveniently collected from the area of the largest pool in the body – the heart and the major vessels connected to it. However, blood in the heart and other central organs (e.g., lungs, liver) is subject to postmortem redistribution (PMR). Drugs that are highly protein-bound tend to concentrate in the major organs such as the lungs, liver, and heart. PMR is the process whereby drugs that concentrate in organs and tissues outside of the blood volume during life are released from those tissues after death, causing blood concentrations of many drugs to markedly increase after death. Not all drugs are subject to PMR, but in varying degrees, a large number are. In general, the extent of PMR will generally be less the farther from the central organs blood is drawn. It is therefore good practice to collect at least some volume of blood (e.g., 5–10 ml) from a site remote from the central organs, such as the femoral veins. The volume of blood required for comprehensive postmortem toxicology may exceed 20 ml, especially if several drugs need to be quantitated; therefore, a sample of subclavian or cardiac blood may be collected for the purpose of qualitative drug screening.

Blood should always be collected with a clean (unused) disposable syringe and needle (typically 16 G or larger) from a clearly identified blood vessel rather than a 'blind stick.' A 'blind stick' to the chest can result in the inadvertent collection of pulmonary blood, pericardial fluid, or pleural fluid. Care is particularly important in cases of death involving trauma where the major organs have moved or ruptured and where chest fluid or, worse, bloody abdominal fluid may be drawn.

It is good practice to ligate (tie off) peripheral blood vessels prior to sampling blood. This is to prevent drawing blood from the larger central vessels that may be subject to PMR – for example, when drawing blood from the groin area (i.e., near the iliac–femoral junction). However, there is growing evidence that for at least some drugs, even a properly collected femoral blood sample may be subject to PMR from surrounding skeletal muscle.

Blood Clots

Many cranial injuries are caused by intoxication with alcohol or drugs. The collection of a blood clot from a subdural hematoma can provide evidence of an alcohol or drug concentration closer to the time of the original injury. Blood which leaks from a damaged blood vessel as a result of such injuries will clot in the subdural space and no longer be subject to normal circulation and clearance. If death is delayed, for example, due to medical treatment, an elevated subdural clot alcohol or drug concentration may provide useful information. Unfortunately, the drug concentration will not persist indefinitely but will diminish over a period of hours or days due to diffusion from the clot into surrounding tissue.

Containers, Preservative

It is good practice to collect at least 5–10 ml postmortem blood into a container that results in a sodium or potassium fluoride concentration of 1–2%. Fluoride inhibits ethanol formation from microbiological metabolism of glucose and similar substrates. However, fluoride also inhibits the action of esterases and will therefore impede the breakdown of some drugs such as cocaine. It should be noted that most gray-stopper clinical blood collection tubes only contain sodium fluoride equivalent to 0.25%.

However, a much larger blood sample (e.g., 30–80 ml) may be collected into a plain screw-capped container with no preservative. Addition of an anticoagulant is usually not necessary because the blood-clotting system is no longer vital after death and the extent of clotting is relatively limited.

Blood collected for the analysis of volatile solvents or gases should be collected into a glass container with tight sealing cap with polytetrafluoroethylene (PTFE) or similar liner.

Trauma, Medical, and Other Artifacts

Caution must be exercised during the collection of blood from areas of the body where significant trauma has occurred or drug administration has taken place. Trauma may result in rupture of the stomach, causing contamination of the entire abdominal cavity, including the area adjacent to the junction of the femoral and iliac veins. Rupture of the stomach and diaphragm can cause spillage of gastric contents into the chest cavity, especially after falls from a height or motor vehicle accidents. The integrity of such chest cavity specimens is always extremely suspect and susceptible to contamination.

Antemortem Blood and Serum

In cases where death after an intoxication, poisoning, or other event has been delayed due to medical treatment, postmortem drug concentrations will be an inaccurate measure of the drug present at the time of the event (if indeed the drug is still present at all when death occurs). Blood, serum, or plasma collected on first admission to an emergency department can therefore provide valuable toxicological evidence. Even if the death occurs fairly quickly after medical treatment is initiated, antemortem specimens are of value because, by definition, specimens collected right before or around the time of death will not be subject to PMR.

Urine

The main advantages of urine over blood are that the concentrations of many drugs in urine are considerably higher than the corresponding concentrations in blood, and urine is much easier and ‘cleaner’ to deal with analytically than postmortem blood.

A disadvantage of urine is that the parent drug is sometimes absent due to extensive metabolism, placing reliance on identification of metabolites. Further, there is virtually no correlation between urine drug concentrations and pharmacological effect. Attempted ‘normalization’ of urine drug concentrations

to creatinine does little to improve their usefulness. Ethanol is one of the few exceptions, where measuring urine concentrations can serve as a corroborative finding of a positive blood concentration (absent glucose in a poorly controlled diabetic).

However, while urine may sometimes be a useful specimen for postmortem toxicology screening, laboratories should not rely on it since the bladder may spontaneously empty during the process of dying.

Vitreous Humor

Vitreous humor is the primary fluid that makes up much of the interior volume of the eyeball – about 3 ml per eye – and is composed of 98–99% water. Vitreous humor is useful for the postmortem measurement of alcohol because it remains sterile for days after death and is therefore not subject to artifactual alcohol formation (unlike postmortem blood). Due to the higher water content of vitreous compared to whole blood, at equilibrium, vitreous alcohol concentrations are typically 10–15% higher.

Vitreous fluid has also been used for the measurement of drugs. However, its use is limited by two factors. First, the volume available is usually limited to about 6 ml, even if both eyes are used. The second factor is that vitreous drug concentrations can be very different from the corresponding whole blood or plasma concentrations. Concentrations of highly lipid soluble or highly protein-bound drugs tend to be much lower in vitreous fluid, due to the relative absence of lipid material and much lower protein content than whole blood.

The measurement of drugs in vitreous fluid has also been touted as a way of avoiding the complexity of interpretation when using whole blood, as the eyes are remote from the major abdominal and chest organs thought to be responsible for PMR. However, these assumptions should be viewed cautiously as PMR from the brain is at least a theoretical possibility.

Bile

In a person whose gall bladder has not been surgically removed for medical reasons, the volume of bile available typically ranges from about 5 to 20 ml, but can be larger. Bile tends to concentrate many drugs, in particular those that form glucuronide and other conjugates, such as morphine. However, that apparent benefit is no longer useful, because modern methodology can detect and measure even subtherapeutic concentrations of most drugs in blood using gas chromatography/mass spectrometry (GC/MS) and liquid chromatography/mass spectrometry (LC/MS) methodologies.

However, bile, like urine, is not a circulating fluid and therefore not in constant equilibrium with blood. Bile is also likely subject to the postmortem diffusion of drugs from the liver.

The Liver

The liver has long been used as one of the primary specimens for drug measurement and interpretation. It is a large organ that tends to concentrate many drugs and is relatively easy to

homogenize. Most importantly, the literature contains a substantial amount of data regarding liver concentrations of drugs in various types of postmortem cases. Care must be taken to differentiate high liver drug concentrations resulting from an acute ingestion or overdose from high concentrations resulting from impaired metabolism or clearance. Some regard the liver as a more useful specimen than postmortem blood for drug measurement because, with one exception, it is not subject to PMR. The exception is that high concentrations of drug in the stomach can diffuse across the stomach wall and causes local increases in the lobes of the liver that are the closest (e.g., left lobe).

It is important that efficient homogenization occur using a high-efficiency blender that uses shearing and sometimes ultrasonic action. It is also important that the whole homogenate be used for quantitative analysis and not just the supernatant. That is because a large proportion of drug will be bound to the cell wall and other cellular structure and would result in a disproportionately low result if only the supernatant were used.

The Brain

The brain is a potentially useful tissue for postmortem drug analysis. Many drugs tend to concentrate in the brain relative to blood, and it is a very easy specimen to homogenize. Being remote from the stomach, it is not subject to postmortem diffusion or PMR from any other organs. The database of brain drug concentrations in the literature is considerably smaller than for the liver. However, the brain is a particularly useful organ for the measurement of drugs that are subject to rapid enzymatic hydrolysis in whole blood, due to esterases (e.g., cocaine, heroin, or 6-acetylmorphine).

Some practitioners are also reluctant to homogenize and analyze brain samples routinely, because of the small but serious risk of exposure to Creutzfeldt–Jakob disease.

Lungs

The use of pulmonary tissue typically has little or no advantage over the liver or brain for measuring drug concentrations. Also, pulmonary tissue is more fibrous than liver and an adequate database of known drug concentrations is lacking that might aid interpretation. Lung tissue has been collected for the analysis of volatile poisons (e.g., solvents, gases). However, unless death occurs very quickly, much of the volatile agent may be absorbed into the body or lost to the atmosphere before the autopsy occurs.

The Kidney

Kidney tissue has also periodically been collected and analyzed in postmortem cases. As a tissue for measuring drug concentrations, it has little if any advantage over liver and the database of blood drug concentrations is considerably smaller than for liver. The kidney has been most often used for measuring concentrations of heavy metals, especially where long-term toxicity is suspected (as compared to acute poisoning).

Skeletal Muscle

Skeletal muscle is the largest mass of soft tissue in the body and is usually the last to survive the process of putrefaction and decomposition. Skeletal muscle tends to be more fibrous than liver or brain. It is moderately well perfused, suggesting the possibility of a reasonably good relationship between skeletal muscle and blood drug concentrations. Again, the disadvantage of skeletal muscle is lack of a good database of 'normal' (i.e., 'therapeutic') or toxic concentrations, although extremes of concentration may be easier to interpret. The limited data that have been published on skeletal muscle drug concentrations suggest that there is at least some site-to-site variation.

Other Tissues and Fluids

Gastric Contents

Gastric (stomach) contents can be useful for helping to determine if an overdose has been consumed, or even simply for the detection of drugs. Analysis of gastric contents is most useful where ingestion of an overdose is possible. In these circumstances, considerable dilution of the stomach contents may be necessary, therefore diluting out the potential matrix effect of a large amount of food. In evaluating the results of gastric drug concentrations, it is critical to keep in mind that it is the total amount of drug present that is important, not the concentration of drug. It should also be kept in mind that stomach contents are rarely homogeneous as a specimen, and may contain wholly or partially digested pills. Therefore, to maximize accuracy, the entire stomach contents should be collected and homogenized prior to analysis. If this is not practical, then a best effort to mix the stomach contents should occur prior to sampling at autopsy, and the total volume that is present recorded. It should also be borne in mind that the presence of only a small amount of drug in the gastric contents does not preclude the possibility of oral consumption of an overdose. Death of a drug overdose victim can take several hours, during which time the stomach may be largely emptied of drug.

Cerebrospinal Fluid

Cerebrospinal fluid (CSF) is similar in composition to vitreous fluid, containing a high water content (98–99%). While CSF can be used for alcohol and drug analysis, it is more difficult to collect after death and can be contaminated with blood. The published data for drug concentrations in CSF are considerably more limited than for vitreous fluid, making interpretation challenging.

Pericardial Fluid

Pericardial fluid is a clear, colorless to straw-colored fluid that is contained in the pericardial sac that bathes and surrounds the heart. Some toxicologists have advocated using pericardial fluid for drug quantitation. However, very few data exist in the literature to aid with interpretation of the results obtained. Due to its intimate proximity to the heart, pericardial fluid is almost certainly subject to postmortem diffusion from the heart and

lungs. Moreover, little is known about how quickly pericardial fluid drug concentrations would equilibrate with the blood.

Chest Fluid and Pleural Cavity Fluid

Pleural cavity fluid is analogous to pericardial fluid, in that it is the fluid in the pleural sac that bathes the lungs. After death, pleural fluid can easily become contaminated with blood, and it will be affected by postmortem diffusion from the lungs. 'Chest fluid' is regarded as any fluid found within the chest cavity. It is sometimes collected when blood is difficult to obtain from a specific vessel such as the femoral or subclavian vein. Chest or pleural cavity fluid may be contaminated with blood or, worse, stomach contents, if the diaphragm and stomach have ruptured. In other words, pleural cavity and chest fluid should be regarded as poor-quality specimens and any quantitative drug concentration derived from those fluids interpreted with extreme caution.

Heart Tissue

Myocardial tissue offers little advantage over other organ tissue for the routine analysis of postmortem drug concentrations. It tends to be more fibrous than some other tissues and a very limited database of published myocardial tissue drug concentrations exists to aid interpretation.

The Spleen

The primary reason spleen tissue has been collected is for the high concentrations of red blood cells it contains. For example, in some fire deaths the heat produced may denature most or all of the readily available blood that might otherwise be collected. However, spleen tissue, partially protected inside the abdominal cavity, may contain enough red blood cells to allow measurement of carboxyhemoglobin (indicating the extent of inhalation of carbon monoxide and other products of combustion into the body during a fire).

Hair, Nails, Bone, Bone Marrow, and Cartilage

Hair is occasionally useful in postmortem toxicology for differentiating chronic from acute drug use, especially in criminal cases. Traditionally, head hair grows at a rate of about $1\text{--}1.5\text{ cm month}^{-1}$. By careful collection and segmental analysis, it is possible to estimate when drug use started or finished, or whether the drug detected resulted from an acute dose shortly before death (because of its absence in the hair). However, analytical toxicology testing of hair is not widely performed, other than for a small range of drugs of abuse, and is rarely performed on postmortem cases except in specific, typically criminal, cases.

Nails can also be used to analyze for drugs, but it seldom has any advantage over other specimens. The analytical protocols used for nail clippings would be similar to those used for hair.

In certain types of postmortem cases, hair, nails, bone, and possibly bone marrow may be all that remains of a body. If the body is not discovered for several weeks, animal activity may consume all of the internal organs, and eventually all skeletal muscle, leaving only skeletal remains (bone, bone marrow,

and perhaps cartilage). Bone can be analyzed for the presence of drugs, much as nails or hair can. Bone needs to be thinly shaved or ground to a powder in order to be extracted and analyzed. If death of the person was rapid, due to an acute poisoning or overdose, detection will depend on how well perfused the specimen was. In theory, detection in bone marrow stands a fair chance of success because bone marrow is well perfused during life. However, detection of a drug resulting from a single acute dose in a poorly perfused specimen like bone may stand only a poor chance of success.

Injection Sites

Suspected injection sites may be excised and submitted for toxicology testing, although pathologists and toxicologists must be careful about interpretation of the results. Most drugs are widely distributed through the body, including all of the major organs, muscle, and, not least, skin. Therefore, a drug would be expected to be found in any skin sample, regardless of the route of ingestion into the body. It is therefore critical that if analysis of a suspected injection site is to be undertaken, a corresponding skin sample must be collected from a 'control' site on the opposite side of the body where injection is not suspected to have occurred. A good example is testing for a possible insulin overdose.

Maggots

Several papers have been published describing the collection and analysis of maggots from a dead body. Putrefaction of a body can complicate the detection of drugs. A body lying unattended for more than a few hours will attract flies that will lay eggs on the body. The eggs will mature into larvae, the resulting maggots that will feed on the body, and so ingest drugs that are present in body tissues and fluids. The maggots can be collected and analyzed, in the same manner as any other tissue or fluid. The problem is that maggots metabolize drugs. Failure to detect a drug does not necessarily mean that the drug was not present in the body at the time of death. Therefore, the analysis of maggots for the presence of drugs is largely regarded as being of limited forensic value.

Special Considerations

Putrefaction

The decomposition of a human or animal body after death causes proteins, fats, and other substances to break down into smaller molecules. That process is partially caused by naturally autolytic enzymes such as lysozymes (contained within each cell), and similar enzymes contained in bacteria. The net effect on postmortem drug concentrations is to make analysis of body fluids and tissues difficult due to greatly increased amounts of putrefactive amines and lipids. Nonetheless, from the perspective of postmortem specimen collection, there is little that can be done except than to rely on the use of tissue from the major organs. Successful testing relies on good design of the analytical method. The majority of drugs are amine-like in character, and so they are relatively easy to separate from fats. However, if putrefaction is advanced, separation of

amine-like drugs from putrefactive amines during the extraction step becomes next to impossible and so highly specific analytical methods such as mass spectrometry must be used. Despite the problems that putrefaction causes, collection of the available postmortem specimens may still allow meaningful analysis an interpretation for some drugs.

Embalmed Bodies

The embalming process creates special problems. Embalming fluid, containing formaldehyde, methanol, isopropanol, detergents, dyes, and other substances is forced into the body through the major blood vessels and also introduced directly into the major organs and body cavity. In the process, much of the blood in the body is flushed out or diluted with embalming fluid. Tissues are 'fixed,' causing the organs to harden. In an embalmed body, the collection of blood is usually not possible. Vitreous fluid in the eye is somewhat protected from the embalming process, and may be collected. However, at the very least, methanol from embalming fluid will usually penetrate the eye as embalmers typically take special care to perfuse the facial area in order to preserve the 'look' of the person.

The collection and analysis of major organs such as the liver may be valuable. However, the toxicologist should be careful to take into account the potential dilution effect of embalming fluid, as well as the fact that formaldehyde can react with some drugs, causing the concentration to decrease or to disappear.

Labeling

All specimens, particularly blood, must be properly labeled with a unique case identifier (usually case number and decedent name), the name of the specimen, and, where appropriate, the location the specimen was collected from (e.g., for blood, whether femoral, subclavian, and aorta). If two containers are collected of the same specimen type (e.g., two tubes of femoral blood), it is important to uniquely label each tube (e.g., #1, #2, #3, or A, B, C). This is particularly important for postmortem blood because it is not a homogeneous fluid; sequentially drawn specimen from the same site may contain different concentrations of drug. It is important that the exact site of draw must be indicated, and not simply terms like 'peripheral' or 'central.' For example, to some, 'peripheral' simply means any blood vessel outside of the heart itself and may, erroneously, be interpreted to include subclavian, inferior vena cava, and aorta blood.

Chain of Custody

The requisition accompanying the specimen to the laboratory should contain the necessary demographic information, as well as sufficient information for the laboratory to decide which specific tests should be performed on a specimen or case. Unless specimens are being transported internally, they should be either individually sealed or the bag or box containing multiple specimens from a single case sealed as part of the chain of custody. The requisition should also be signed and dated by the person responsible for collecting and releasing the specimens for transfer or transport, and should be signed and dated by the person accepting receipt of the package in the laboratory. In most jurisdictions, documentation of courier transportation is accepted as part of the intermediate transport chain of custody (i.e., the courier is not required to sign the requisition as part of the chain of custody documentation).

Introduction

Plants have been used by humans for their mind-altering properties for a long time. Products taken for such nonmedical reasons are called drugs of abuse. Most commonly abused substances that are extracted from or based on natural products are the classical drugs of abuse such as cannabis products, morphine, or cocaine.

In addition to these classical drugs, the so-called herbal or natural drugs consist of plant material with psychoactive properties. In recent years, the herbal drugs of abuse have become increasingly popular among drug abusers, largely due to publicity on the Internet.

The publicity has also sparked a development of synthetic drugs being introduced under the banner of 'herbal' or 'legal' highs. In order to sell psychoactive products, synthetic cannabinoids have been sprayed on nonpsychoactive plant mixtures.

However, as in the case of classical drugs of abuse, abuse of plants or plant ingredients may cause psychiatric problems like addiction or chronic illnesses. Depending on the pharmacological activity of the contained active ingredients, they may even cause serious acute intoxication and poisoning, especially in overdose situations.

This article describes common herbal drugs of abuse in monographs. The monographs contain descriptions of the plants, their pharmacologically active compounds, and the current knowledge of their pharmacological properties.

Traditional Drugs of Abuse of Herbal Origin

Cannabis and Tetrahydrocannabinol

Cannabis is derived from *Cannabis sativa* L., a herbaceous annual plant. The species *C. sativa* can be divided into a number of subspecies and varieties. The plant is highly recognizable: the leaves are typically separated into five or more serrated leaflets. The stem of the plant is extremely fibrous and is therefore a popular source of fabric fiber.

Chinese medical records report the use of cannabis as far back as 2737 before common era (BCE). The plant was also known on the Indian subcontinent and the Arabian Peninsula, before the start of the common era as a herbal remedy. Medical records show that cannabis was used as an antimalarial and antirheumatic drug, a narcotic, an aphrodisiac, a carminative, and as a remedy to treat nausea and headache.

Different varieties have become popular as commonly used drugs of abuse. Sinsemilla is a seedless, more potent form produced from the unfertilized flowering tops of female cannabis plants, often found in the United States. Other forms of cannabis include Thai sticks, hashish (resin), and oil (hash oil). Modern names used to describe cannabis include 'weed,' 'grass,' 'dope,' 'dagga,' and 'pot.'

The plant prefers a warm humid climate, although it will grow in most climates. However, indoor and glasshouse cultivation are required for the cooler climates. The cannabis plant is dioecious, with male and female flowers borne on separate plants.

The pharmacologically active compounds contained in cannabis are the cannabinoids, a group of at least 66 substances. The most psychoactive cannabinoid in cannabis is Δ^9 -tetrahydrocannabinol (THC).

All parts of the plant contain THC including flowers, leaves, seeds, and stalks. Oil is produced from the seeds and flower heads. The female plant is known to be more robust, produces larger flowers, and, importantly, contains a higher THC content.

Cannabis as a drug of abuse is used mainly by smoking in the form of cigarettes (joints) or using cold-water pipes (bongs). Baking 'cookies' with the use of hash oil is also widespread. Procannabinoids that can be found in the plant material are converted to THC by heat.

When smoked, common single doses of cannabis are 50–100 mg. The rapid onset of action (within 10 min) assists in the dosage of cannabis and additional intakes are smoked until the desired effect is achieved. The total duration of action of smoked cannabis is 1–4 h.

Pharmacological effects of THC include an increase in heart rate, blood pressure, and body temperature. More importantly, the ingestion of THC-containing smoke produces a range of cognitive and psychomotor effects associated with a transient euphoric effect that is usually perceived as a 'high.' Short-term memory loss can occur particularly with repeated use.

The cannabinoids are ligands of the cannabinoid G-protein-coupled receptors. Evidence for the existence of a human cannabinoid receptor was found in the mid-1980s, and the cannabinoid receptor subtype 1 (CB₁) receptor was confirmed by cloning in 1990. A second cannabinoid receptor, the cannabinoid receptor subtype 2 (CB₂) receptor, was confirmed by cloning in 1993. The CB₁ receptor is predominantly found at central and peripheral nerve terminals, whereas the CB₂ receptor is mainly distributed in immune cells.

With the discovery of cannabinoid receptors, the question arose as to whether these receptors had endogenous ligands or whether they were targets only for THC and other plant cannabinoids. The first endogenous cannabinoid was described in 1992. The substance was identified as arachidonoyl ethanolamide and named anandamide. So far, five endogenous cannabinoid receptor agonists have been described.

Coca and Cocaine

Coca is a plant from the genus *Erythroxylum* and is native to northwestern South America. The use of coca has a long tradition in South America. The first European description of coca is from Amerigo Vespucci from 1499; he described how South American aborigines would chew the leaves to overcome fatigue and hunger.

The most important alkaloid in the coca plant is cocaine, first isolated in 1859 by Albert Niemann, a German chemist. The leaves contain up to 2% cocaine in a dried state. Although the genus *Erythroxylum* includes several hundred species, only *Erythroxylum coca* and *Erythroxylum novogratense* contain significant amounts of cocaine. Trace amounts of cocaine have recently been detected in 23 species of *Erythroxylum*, but with content below 0.001%.

In 1863, the Italian chemist Angelo Mariani introduced a coca extract in sweet wine as a tonic, the so-called Vin Mariani. This tonic was copied in 1884 in the United States by John Pemberton. One year later, Pemberton responded to the American Prohibition legislation by developing a nonalcoholic carbonated coca extract called Coca-Cola, which contained an estimated amount of 9 mg of cocaine and was on the market until 1903.

The use of coca leaves as a local anesthetic was first proposed by Samuel Percy in 1856. After the isolation of cocaine, the Austrian pharmacologist Karl Damian Ritter described narcotic effects after application on the skin. About 25 years later, cocaine was used in clinical practice as a local anesthetic in ophthalmic surgery. The advantage of cocaine as a local anesthetic is its unique combination of local anesthesia and intense vasoconstriction. Therefore, cocaine is still used for topical anesthesia by otorhinolaryngologists.

The safe maximum dosage as a local anesthetic for a cocaine-naïve person is reported to be 200 mg or 2–3 mg kg⁻¹; however, this is based on anecdotal observations rather than controlled studies. Cocaine doses as low as 20 mg can cause adverse reactions if rapidly absorbed.

The onset of cocaine action is very fast and the half-life of cocaine is less than 1 h; therefore, combined with a strong reinforcing action, cocaine causes a rapid psychological dependence.

The anesthetic effects are pharmacologically caused by blocking of sodium channels, whereas the vasoconstriction is caused by sympathetic activation. Cocaine inhibits the reuptake of catecholamines, which increases the activity of sympathetic synapses. This stimulation also occurs in the brain; therefore, cocaine causes euphoria, garrulousness, and increased motor activity. Cocaine also decreases fatigue and is abused as a stimulant.

Poppies and Opiates

Poppies include a number of attractive wildflower species, of which many species are also grown in gardens. Of all the different poppy plants, the opium poppy or *Papaver somniferum* is

pharmacologically the most important. *P. somniferum* is an annual plant with a simple or only slightly branching stem. The leaves are ovate-oblong and of gray-blue greenish color. The flower can vary in color; pink varieties are the most common. Incisions made in the unripe capsules of *P. somniferum* release white latex that quickly hardens and turns brown after contact with oxygen. The hardened brown latex is called raw opium; each capsule releases ~20–50 mg.

The main active alkaloid in opium and other parts of *P. somniferum* is morphine, which was first isolated in 1806 by the German pharmacist Friedrich Sertuerner. He called the isolated alkaloid 'morphium' after the Greek god of dreams, Morpheus. It was not only the first alkaloid to be extracted from opium, but the first alkaloid ever to be isolated from any plant. With the invention of the hollow needle and the syringe, morphine was used in the treatment of postoperative and chronic pain, and as an adjunct to general anesthetics. Unfortunately, morphine had as much potential for abuse as opium. Looking for a safer and nonaddictive opiate, Felix Hofmann synthesized diacetylmorphine in 1898. From 1898 to 1910, diacetylmorphine was marketed by Bayer under the brand name heroin. The drug was promoted as a nonaddictive morphine substitute and cough medicine for children.

The abuse of opioids was common in the late nineteenth century, leading to the International Opium Commission meeting in 1909 (in Shanghai) as the first step toward international drug prohibition. Based on this meeting, the first international drug control treaty, the International Opium Convention, was signed in 1912 at The Hague. This convention went into force globally in 1919, when it was incorporated into the Treaty of Versailles. Today, opium and opiates are controlled by the International Narcotics Control Board of the United Nations under Article 23 of the Single Convention on Narcotic Drugs, and subsequently under the Convention on Psychotropic Substances. Opium-producing nations are required to designate a government agency to take physical possession of illicit opium crops as soon as possible after harvest and conduct all wholesaling and exporting through that agency.

Emerging and Popular Herbal Drugs of Abuse

Nightshades

Atropa belladonna

The perennial plant *A. belladonna* is commonly known as deadly nightshade. Other common names such as dwale, death's herb, or witch berry give an impression of its toxicity and use in the middle age. The pharmacological effects of the plant are part of the etymology of the botanical name. The genus *Atropa* is named after the goddess Atropos, who is known in Greek mythology to cut the life thread. The species name *belladonna* is Italian for beautiful lady, and originates from its historical use of the berry juice by women to dilate their pupils.

All parts of *A. belladonna* contain psychoactive tropane alkaloids. The main alkaloids present in *A. belladonna* are L-hyoscyamine and L-scopolamine. Even though only L-hyoscyamine is present in the plant, L-hyoscyamine is converted to a racemic mixture of 50% L-hyoscyamine and D-hyoscyamine. This conversion is either a result of extraction or release after ingestion. This racemic mixture is called atropine.

Atropine acts pharmacologically via blocking acetylcholine receptors of the muscarine subtype. The blockage of these receptors causes symptoms like tachycardia, dilated pupils, decreased gastrointestinal motility, and dry hot skin and dry mouth due to a decreased sweat and saliva production. Apart from these peripheral effects, atropine also affects the central nervous system and causes agitation, disorientation, and hallucinations, which explain the common abuse of the herb.

Commonly abused parts of the plant are leaves and berries in doses of approximately 0.2 g of dried matter. The abuse has often been described as an unpleasant experience when the dose was too high. The plant is described to show a long duration of effects, often up to 36 h when untreated.

Datura stramonium

The annual plant *D. stramonium*, which is often found in nutrient-rich soils, grows to a height of up to 1 m. This plant of the nightshade family is commonly known as Thornapple, Jimsons Weed, or Angel's Trumpet. The large flowers of *Datura* are white, erect, and tubular. The tubular shape and its psychoactivity are related to the name Angel's Trumpet. The name Thornapple is related to the fruits which are spiky large green capsules containing numerous black seeds. The plant is distributed generally throughout the temperate and subtropical regions. Similar to *Datura* in botanical appearance are the *Brugmansia* species, which are often cultivated in pots as house plants.

All parts of *Datura* and *Brugmansia* contain the psychoactive tropane alkaloids as already described for *A. belladonna*. The increasing misuse has forced a prohibition by law in Florida of planting Angel's Trumpets.

Commonly abused parts of *Datura* are the dried flower petals (smokes) or the seeds (oral ingestion). Dosage, effects, and duration of effects are similar to those after the ingestion of *Atropa*.

Kath (Catha edulis)

The evergreen shrub *C. edulis*, which is native to tropical East Africa and the Arabian Peninsula, is known as khat or qat. In these countries, therapeutic and recreational khat use has been an integral part of local culture for centuries. In the second part of the twentieth century, the consumption changed to an uncontrolled abuse and spread throughout other continents. In 1980, the World Health Organization classified khat as a drug of abuse capable of causing dependence.

The main psychoactive alkaloids of khat are cathinone and its metabolite cathine, also known as norpseudoephedrine. Cathinone was found to have a pharmacological profile closely resembling that of amphetamine. Cathinone acts as a central nervous system stimulant and shows sympathomimetic effects on releasing catecholamines from presynaptic storage sites. Experiments have shown that cathine acts like cathinone, but is less effective. Both are controlled substances in many countries due to khat abuse.

The fresh leaves are chewed as soon as possible after harvesting. Khat has been used traditionally as a stimulant in Ethiopia by older men in conjunction with religious rites. Today, khat leaves are chewed by men and women of all ages, mostly in countries where khat is grown. But in other countries too, emigrants try to maintain this habit. Therefore,

large quantities of fresh leaves are illegally imported to other countries. Common doses are in excess of a few grams of fresh leaves and are chewed over a prolonged period of time.

In recent years, designer drugs based on the chemical structure of cathinone have emerged in the illicit drug market. Methcathinone was the first cathinone derivative which was synthesized in 1928 as an intermediate of the synthesis of D,L-ephedrine. Shortly after, mephedrone (4-methylmethcathinone, 4-MMC) was synthesized by a French chemist Saem de Burnaga Sanchez in 1929, but the compound was later considered to be an obscure chemical product. Prior to the widespread abuse of cathinone derivatives, some substances, namely bupropion, amfepramone, and metamfepramone, were marketed as appetite suppressants and in the case of bupropion, as a drug for smoking cessation. To date, these substances are still prescribed and also abused as anorectic drugs.

Salvia (Salvia divinorum)

S. divinorum is a herbaceous plant, native to the Mazatec region of the Sierra Madre Oriental in the Mexican state, Oaxaca. This plant has been used in traditional spiritual practices by Mazatec aborigines in a manner very similar to magic mushrooms (*Psilocybe* spp.). The plant and its use were discovered by the West in 1962 by Gordon Wasson, followed by the first botanical description by Carl Epling and Carlos Játiva-M. in the same year. Shortly after the first botanical description of the plant and its psychoactive properties, Albert Hofmann tried to discover the active constituents by analyzing the juice pressed from the plant. His analysis was unsuccessful, and it took until 1982 to isolate the diterpenes salvinorin A and salvinorin B. So far, 14 diterpenes have been isolated from *S. divinorum*, but salvinorin A seems to be the major active compound. Even though the plant is closely related to common sage (*S. officinalis*), neither an essential oil nor thujone, common in other *Salvia* species, has been detected in *S. divinorum*.

In 1994, Daniel Siebert showed that the leaves of *S. divinorum* have psychoactive effects when the ingredients of the juice are absorbed via oral mucosa. The plant material was inactive when swallowed as quickly as possible to bypass the oral mucosa. In this study, the author also showed that salvinorin A produced the same psychoactive effects as the plant juice. Some years later, in 2002, salvinorin A was found to be a potent and the first nonnitrogenous agonist of the κ -opioid receptor, whereas salvinorin B is inactive at this receptor. In recent times, the availability of the plant has increased rapidly, partially due to Internet trading. Within a few years, *S. divinorum* has become a popular herbal drug of abuse.

The unique pharmacology of salvinorin A as the first non-nitrogenous opioid receptor agonist and its popularity as a drug of abuse has substantially increased researchers' interest in it.

Dried leaves of *S. divinorum* or concentrated extracts are commonly smoked leading to a rapid onset of action. The peak of effects is experienced after 1–5 min, and the experience is described to have a duration of less than 15 min.

Iboga (Tabernanthe iboga)

The perennial rainforest shrub *T. iboga*, commonly known as iboga, is native to central western Africa. The plant reaches about 1.5–2 m in height and has yellowish or pinkish flowers

that turn into sweet fruits which do not contain psychoactive alkaloids. The plant is a sacrament and symbol of power in the Bwiti religion, with the roots used in religious ceremonies as a 'bridge to the ancestors.' In small amounts (up to 5 mg kg⁻¹), the root is chewed by locals to reduce hunger and fatigue, but larger amounts (10 mg kg⁻¹ or greater) will cause hallucinations and have even caused death.

The root bark contains about 6% indole alkaloids: primarily ibogaine (12-methoxyibogamine), and also tabernanthine, ibogaline, and ibogamine.

Ibogaine is a noncompetitive antagonist at $\alpha 3\beta 4$ nicotinic receptors and a sigma₂ receptor agonist, increases ribonucleic acid expression of glial-cell-line-derived neurotrophic factor, is a weak agonist on the serotonin 5HT_{2A} receptor, and is a weak *N*-methyl-D-aspartate receptor antagonist. The major metabolite, noribogaine (12-hydroxyibogamine), is a potent serotonin reuptake inhibitor and is also a moderate kappa and weak mu opioid receptor full agonist. Ibogaine has also been used to treat dependency on alcohol and illicit drugs, although its efficacy is questionable.

Morning Glory and Lysergic Acid Amide

Morning glory is a common name for over 1000 species of plants in the family *Convolvulaceae*. If morning glory is abused, the plant is probably either *Ipomea tricolor* or *Rivea corymbosa*. Both plants are perennial twinning lianas native to Central and South America. The seeds of both plants have been used by Native Americans for their hallucinogenic properties. The seeds of *I. tricolor* have been called *tlilitzin* by Aztecs, meaning 'the very black,' while the seeds of *R. corymbosa* were named *ololiuqui*, which is translated as 'that which causes turns.' Nowadays, the most commonly used term for the seeds of *I. tricolor* is *badoh negro*, and for the seeds of *R. corymbosa*, *badoh blanco*.

The fresh or dried seeds are ground and mixed with water and ingested orally. After ingestion, the seeds produce psychedelic effects similar to those of *Psilocybe* mushrooms or lysergic acid diethylamide (LSD). The hallucinogenic effects of a cold water extract are not exactly the same as those of LSD, but visions of 'small people' is typical. Eating the seeds can cause side effects such as nausea and vomiting, probably induced by nonwater-soluble alkaloids.

In 1960, Albert Hofmann isolated ergot alkaloids like lysergic acid amide from *R. corymbosa*. The psychoactive effects of lysergic acid amide, also called ergine, were assessed by Albert Hofmann by self-administration back in 1947, well before this was discovered to be a natural compound. He described a tired, dreamy state with an inability to maintain clear thoughts after intramuscular administration of 500 mg of ergine.

Lophophora williamsii

The small spineless cactus *L. williamsii* is commonly known as peyote. This cactus grows extremely slowly and flowers sporadically. In the wild, it takes up to 30 years to reach the size of a golf ball, and to produce the first flowers. The small pink fruits of peyote are sweet-tasting and delicate. The cactus is native to southern United States and Mexico, but is cultivated all over the world.

A recent study has shown prehistoric use of peyote by native North Americans. A radiocarbon study dated dried cacti, so-called mescal buttons, to the time interval 3780–3660 BCE. Because psychotropic alkaloids were present in these dated buttons, it was concluded that they were used for their psychoactive effects.

The main reason for the psychoactive effects of peyote is the presence of the phenethylamine alkaloid mescaline. The effects of peyote and mescaline in humans are well studied. Native peyote cults used the cactus because it produces rich visual hallucinations. These effects were also used in psychiatric studies as a chemically induced model of mental illness. The mechanism of action is similar to that of LSD or psilocin. These substances act as partial agonists at 5-hydroxytryptamine receptors.

The abuse of peyote is mainly by oral ingestion of the dried cacti. Although the acute toxicity of peyote or mescaline is not as high as other herbal alkaloids, fatalities are described. Due to the strong hallucinations, fights among drug abusers or self-harm situations are not uncommon.

Piper methysticum

The common English name for the western pacific plant *P. methysticum* is kava. Other names for the plant are 'awa,' used in Hawaii, or 'yaqona,' common in Fiji. Kava is an evergreen bush growing up to 3 m tall, with heart-shaped leaves up to 20 cm in length. The plant is closely related to black pepper (*Piper nigrum*) and also has a spicy taste. Kava is psychoactive, indicated by the scientific species name *methysticum*, which is Greek for intoxicating. Kava is consumed on many western pacific islands and in Australia. Traditionally, kava is prepared by grinding or chewing the rhizome, which is mixed with water or coconut milk. The effects after consumption of kava are talkative and euphoric behavior, anxiolytic effects, a sense of well-being, clear thinking, and relaxed muscles. The plant contains a mix of kavalactones and kavapyrones. Extracts of the plant were introduced into modern medicine as a mild anxiolytic. After the report of some deaths due to its medicinal use, kava medicines were banned. Kava-containing medicine causes acute liver failure. The traditional use of kava by Pacific Islanders and by some aboriginal communities is not believed to be associated with liver damage. A recent study has shown that kava fed to rats does not cause liver damage. Further investigations are necessary to demonstrate the long-term safety of kava preparations.

Traditional kava ingestion uses dried kava root powder suspended in water, and common doses are 15–25 g of the dried root.

Analytical Methods

Because of the diversity of the psychotropic compounds in plants, a general laboratory screening procedure is not possible. Therefore, various specific methods for detection have been developed.

Methods for detection of naturally occurring psychoactive compounds include high-performance liquid chromatography (HPLC), liquid chromatography-mass spectrometry (LC-MS),

Table 1 Herbal drugs of abuse listed by their common and scientific names, common routes of ingestion and most important active compounds

Common English name	Scientific name	Common abuse	Active compound (most important)
Coca	<i>Erythroxylum coca</i>	Smoking, intravenous abuse, snorting (free base)	Cocaine
Iboga	<i>Tabernanthe iboga</i>	Oral ingestion (eating roots)	Ibogaine
Kath	<i>Catha edulis</i>	Oral ingestion (chewing leaves)	Cathinone
Kava	<i>Piper methysticum</i>	Oral ingestion (drinking infuse), oral ingestion (herbal pills)	Kavapyrone
Marijuana	<i>Cannabis sativa</i>	Smoking, oral ingestion (eating cookies)	Δ^9 -Tetrahydrocannabinol
Morning glory	<i>Rivea corymbosa</i> , <i>Ipomea tricolor</i>	Oral ingestion (drinking infuse), oral ingestion (eating seeds)	Ergine
Nightshades	<i>Atropa belladonna</i> , <i>Datura stramonium</i> , <i>Brugmansia</i> spp.	Oral ingestion (drinking infuse), oral ingestion (eating berries)	Atropine, scopolamine
Opium poppy	<i>Papaver somniferum</i>	Intravenous abuse, oral ingestion (tablets), smoking (common in Asian cultures)	Morphine, codeine
Peyote	<i>Lophophora williamsii</i>	Oral ingestion (drinking infuse), oral ingestion (eating)	Mescaline
Salvia	<i>Salvia divinorum</i>	Smoking, oral ingestion (chewing leaves)	Salvinorin A

and gas chromatography–mass spectrometry (GC–MS). The use of HPLC is common for detection of compounds like the ingredients of kava, for example, kavalactones and kavapyrones. The modern and more sensitive LC–MS technique has been applied to many naturally occurring substances, especially if low concentrations have to be detected. The use of GC–MS technique is applicable if the substances are thermostable and it provides a powerful tool for detection of alkaloids like atropine, cathinone, and mescaline. While GC–MS techniques are useful, LC–MS techniques are preferred for the detection of low concentrations in blood.

A postmortem detection of the toxic substances is often challenging. Determination of these is best conducted in urine (Table 1).

Summary and Conclusion

Psychoactive plants can be divided into two main categories: the classical psychoactive plants of abuse and the emerging drugs of abuse of herbal origin. The classical herbal plants of abuse have been known for their psychoactive properties for centuries and the isolated active ingredients have developed into the most common drugs of abuse in modern times. In recent years, it has become more and more common to abuse novel drugs of abuse, mainly due to publicly available knowledge communicated over the Internet.

The detection of novel drugs of abuse of herbal origins has become a very challenging part of forensic sciences, especially in analytical toxicology.

Glossary

Adulterant Any foreign substance that modifies the purity or effectiveness of a substance.

Ayurvedic medicine A system of traditional medicine native to India and a form of alternative medicine.

Blood cholinesterase inhibitor A substance that binds to the enzyme cholinesterase and inhibits the biodegradation of acetylcholine, resulting in the potentiation of the action of endogenously released acetylcholine at cholinergic synapses.

Cholinesterase One of many important enzymes responsible for the proper functioning of the nervous systems of humans, other vertebrates, and insects.

Contaminant An unwanted biological, chemical, physical, or radiological substance that makes something dirty, polluted, or poisonous.

Decoction A method of extraction by boiling of dissolved chemicals, or herbal or plant material, which may include stems, roots, bark, and rhizomes.

Hypoglycemia The occurrence of a wide variety of symptoms in association with blood glucose level falling below 4 mmol l^{-1} .

Nephrotoxin A substance having a specific toxic effect on the kidney.

Phosphodiesterase type-5 inhibitors A class of vasoactive drugs that have been developed for treatment of erectile dysfunction.

Phytochemicals Chemicals that occur naturally in plants.

Phytopharmaceuticals Drugs of plant origin or derived from plants.

Therapeutic Having or exhibiting healing powers such as a drug that has healing or curative capability for treatment of disease or disability.

Traditional Chinese medicine (TCM) The name, also known simply as Chinese medicine, commonly given to a range of traditional medical practices originating in China thousands of years ago.

Abbreviations

AAS	Atomic absorption spectrophotometry
AChE	Acetylcholinesterase
AES	Atomic emission spectroscopy
DAD	Diode array detection
ECD	Electron capture detection
GC	Gas chromatography

GUS	General unknown screening
ICP	Inductively coupled plasma
LC	Liquid chromatography
NPD	Nitrogen phosphorus detection
OES	Optical emission spectroscopy
MS	Mass spectrometry/spectrometer
TCM	Traditional Chinese medicines

Introduction

Written historic records such as *Shennong Bencao Jing* in China, *Ebers Papyrus* of the ancient Egyptians, and a treatise called *Sushruta Samhita* of Indian Ayurveda provide evidence of the long history of the use of plant materials either alone or in combination with other plant(s) for medicinal purposes. Although the use of herbal medicines declined in favor of pharmaceuticals in the nineteenth century due to emergence of synthetic pharmaceuticals, there has been an upward trend in the usage of herbal medicines and/or phytopharmaceuticals (a pharmaceutical agent of plant origin) in both developed and developing countries in recent years.

Many people have the perception that the use of plant materials for medicinal purposes is safe and rarely causes adverse toxic effects. However, incidental poisonings with serious or even fatal consequences have been reported from time to time. Apart from those caused by the use of toxic herbs with intended purpose(s), many of them are due to contamination or adulteration, which could happen either accidentally or

intentionally. Such contaminations/adulterations can have important clinical and toxicological consequences and are particularly worrying because they are unpredictable, and often remain undetected unless they can be connected with health issues.

Sources of contamination can be originated from the environment. For example, toxic metals or other naturally occurring radionuclides may be absorbed during the growth of a plant; intentional or accidental usage such as pesticides or toxic pollutants emitted from factories that contaminate the nearby medicinal plants; and the presence of microbial and fungal growth resulting in microbial toxins such as aflatoxins, which are known to be highly toxic and carcinogenic.

Contamination with toxic herbs can occur either as a mix-up with other plants growing in the vicinity that are nontoxic or sometimes during the herbal preparation process due to poor quality control. Accidental herbal intoxication can also occur as a result of using the wrongly identified herbs either as a single plant or mixed with other herbs in compound formulations. Although there are numerous medicinal plants widely

used today, significant numbers of the reported poisoning cases are confined only to a few types of toxic herbs. For instance, aconitine, gelsemine, and tropane alkaloids such as atropine and scopolamine are some of the typically toxic substances found that have caused poisonings or even deaths.

With the belief that herbal remedies can boost an individual's health and alleviate disease in an 'all natural' way and be free from other side effects, poisonings have also been reported in many countries due to intake of herbal remedies which were later found to contain undeclared conventional drugs that are added intentionally in order to exert the claimed therapeutic effects.

Overall, many poisoning cases can be traced back to the use of poor-quality herbal medicines. Unlike most prescription drugs that required testing for safety, quality, and efficacy before putting into the market, herbal medicinal products are usually sold as dietary supplements or natural remedies, which in many countries are not subject to rigorous testing.

In view of the wide diversity of substances that may require toxicological examination in this context, some of the analyses may not be covered in routine toxicological screening procedures. As such, different strategies may be applied to deal with the analytical concerns for cases of intoxication related to herbal medication, and it is often useful if more detailed background information about the case is available.

Common Forms of Contamination/Adulterants

Heavy Metals

Heavy metals are commonly present in our environment. Apart from the accumulation during cultivation of soil, other possible sources of heavy metals found in herbal medicines are the accidental contamination from processing machinery or intentional addition to achieve the desired properties. The most commonly encountered heavy metals in herbal medicines include arsenic, lead, and mercury. The use of toxic heavy metals as mineral drugs has long been prescribed in some traditional medicines such as Calomelas (as mercurous chloride) and Realgar (as arsenic disulphide) in traditional Chinese medicines (TCM), and Talaka (as arsenic trisulphide), Naga bhasmas (as lead sulfide), and Makardhwaja (as mercuric sulfide) in Indian Ayurvedic medicines. To date, many countries have restrictions on the content of heavy metals.

For instance, in Singapore, limits of 20 ppm lead, 5 ppm arsenic, and 0.5 ppm Hg were imposed on herbal medicines. The Hong Kong *Chinese Materia Medica Standards* also lists the general recommended limits of lead, mercury, and arsenic being 5.0, 0.2, and 2 mg kg⁻¹, respectively, in raw herbs. Despite various regulatory measures, herbal preparations containing heavy metal ingredients may still be sold illegally as health products. Intoxications due to intake of high levels of heavy metals in herbal preparations have been reported and some examples are shown in Table 1.

The natural presence of arsenic in herbal medicines should be no different from its wide occurrence in foods. In most cases, the inorganic trivalent form such as arsenious acid (arsenite) is more toxic than the pentavalent form. Arsenic levels can be measured in blood and urine. As arsenic is eliminated fairly quickly from the blood (about 2–4 h after exposure), the use of urine which can detect arsenic within few days of exposure can be considered. An abnormal arsenic level in blood for adults is greater than 100–200 µg l⁻¹.

Mercury intoxication can be due to either contamination or the intentional addition at high levels, as often seen without labeling in cosmetic ointments for whitening of skin. Blood and urine are suitable samples to be used for determining recent exposure to mercury. Liver and kidney function tests are also useful in severely exposed persons. The concentrations of mercury in normal subjects are usually less than 10 µg l⁻¹ in blood.

Lead contamination can induce many adverse health effects such as mental retardation, and cognitive and behavioral problems, particularly in children. It has a half-life of a few months. When a subject presents with symptoms consistent with lead toxicity, blood testing is necessary. Symptoms of lead poisoning in adults may appear when the concentration in blood exceeds 8 µg l⁻¹. For children, a blood level as low as 3 µg l⁻¹ can cause health problems.

Pesticides

Although the intake of herbal medication that causes serious pesticide intoxication is rarely noted, herbal medicines, like other plants, are liable to contain pesticide residues at levels which may be unsafe to humans. Similar to other agricultural products, pesticides can accumulate during cultivation from standard agricultural practices and administering of fumigants

Table 1 Examples of intoxication cases with heavy metals in herbal products

Countries	Herbal products	Findings
Singapore	Antiasthmatic herbal preparations	Arsenic: 25–107 000 mg kg ⁻¹
United States	Traditional Chinese herbal balls	Arsenic: 0.1–36.6 mg per ball Mercury: 7.8–621.3 mg per ball
United Kingdom	Herbal products for homeopathic remedies	Lead: 6.5–7.5 mg per tablet
United States	Ayurvedic herbs	Lead: 5–37 000 mg kg ⁻¹ Mercury: 28–104 000 mg kg ⁻¹ Lead: 37–8130 mg kg ⁻¹

Sources: Tay CH and Seah CS (1975) Arsenic poisoning from anti-asthmatic herbal preparations. *Medical Journal of Australia* 2(11): 424–428; Espinoza EO, Mann MJ, and Bleasdel B (1995) Arsenic and mercury in traditional Chinese herbal balls. *The New England Journal of Medicine* 333(12): 803–804; Olujohungbe A, Fields PA, Sandford AF, and Hoffbrand AV (1994) Heavy metal intoxication from homeopathic and herbal remedies. *Postgraduate Medical Journal* 70: 764; Saper RB, Kales SN, Paguin J, and Phillips RS (2004) Heavy metal content of ayurvedic herbal medicine products. *Journal of the American Medical Association* 292(23): 2868–2873.

during storage. Commonly encountered pesticides in herbal drugs include a variety of insecticides such as organochlorines, organophosphorus, carbamates, and pyrethroids, and herbicides such as paraquat. Permissible or recommended limits of pesticide residues in herbal medicines are usually listed in some pharmacopeias/standards such as the *European Pharmacopoeia* and the Hong Kong *Chinese Materia Medica Standards*.

Pesticides, once deposited into the human body, will undergo various biotransformations. For organophosphorus and carbamate pesticides, they are metabolized rapidly and are excreted mainly as metabolites. Certain organochlorine pesticides may pass through the human body intact but due to their fat solubility will deposit in adipose tissue such that the parent compounds and the associated metabolites may also be detected in blood/serum and adipose tissue. In this regard, it would sometimes be necessary to analyze the metabolites together with the unchanged pesticides to provide clues for the types of poisoning. **Table 2** shows some examples of common pesticides with relevant metabolites.

The analysis of pesticides in body fluids is complicated as certain pesticides may be decomposed by acid or alkali. For instance, organophosphorus and certain carbamate pesticides are susceptible to hydrolysis in alkaline medium while some carbamate pesticides such as carbofuran are unstable in acid. Relevant analytical procedures have been published by the World Health Organization and the *European Pharmacopoeia* for the analysis of pesticide residues in herbal medicines.

Toxic Herbs

Some toxic herbs that are considered to be dangerous in the Western community are often used for treatment of diseases in other parts of the world either in parallel with conventional medications or in situations where modern medicines are considered inadequate for the problem. *Callilepis laureola* (contains atractylodeside) has been used in folk medicine in certain tribes of South Africa to serve as a multipurpose remedy including stomach problems, tapeworm infestations, impotence, and to induce fertility. In TCM, toxic herbs like *Radix Aconiti Lateralis* (contains aconitum alkaloids), which is used for the

relief of pain, have been included in pharmacopeia and in compound formulation. The therapeutic use of these toxic substances is usually prescribed in small doses and the toxicity can be significantly reduced if they are properly processed and prescribed in combination with some other herbal constituents as 'antidote'. In view of the therapeutic usage of these toxic herbs in some herbal medicinal systems, it is not unreasonable to anticipate that the risk of contamination, mix-up, or misidentification would increase, in particular, when persons handling both toxic and nontoxic herbs are not properly trained and qualified.

Occasionally, consumption of nontoxic herbal medicines or remedies causes toxicity relevant to certain toxic herbal ingredients. The cause of poisoning is usually uncovered after review of the clinical presentation, supported by the analysis of the remnants of the herbal medicines, and analysis of biological specimens (such as urine) obtained from the victims. Toxic ingredients commonly encountered include aconitum alkaloids, gelsemine, and tropane alkaloids such as atropine and scopolamine.

A widely used nontoxic TCM called *Rhizoma Atractylodis* contaminated with other toxic herbs containing aconitum or tropane alkaloids has been identified to be the origin of several poisoning cases in Hong Kong. For instance, in one of the cases, morphological examination of *Rhizoma Atractylodis* revealed the presence of another species (**Figure 1**) which was later confirmed to contain tropane alkaloids.

Other examples reported include *Cassytha filiformis* (often used for alleviation of colds and fevers), which was mixed up or contaminated with other plants that grew around it such as *Gelsemium elegans* containing gelsemine; *Radix Strobilanthis Forrestii* contaminated with unknown atropine-containing species; and *Rhizoma Ligustici* contaminated with unknown aconitine-containing species.

Herbal medicines and phytopharmaceuticals are often prepared from one or many species of herbal materials. Misidentification in the handling of herbal materials with similar botanical features or nomenclature can sometimes occur and cause severe intoxication. For instance, the similarities in appearance and common name between *Stephania tetrandra* ('han fang ji') and the toxic *Aristolochia fangchi* ('guang fang ji') (containing aristolochic acid, a nephrotoxin) have been reported to be related to a number of intoxications resulting in nephropathy (**Figure 2**). Another example that caused a cluster of intoxication events in Hong Kong is the case in which *Flos Campsis*, a nontoxic herb, was substituted with *Flos Daturae Metelii*, a toxic herb containing atropine, in a decoction prescription due to their similar appearances (**Figure 3**). **Table 3** summarizes some reported incidents to be related to mix-up or misidentification of toxic herbs.

Commonly confused species can be found in literature with detailed description of the morphological features of each species. As such, identification of substitution of herbal materials can be achieved through morphological (macroscopic and microscopic) examination together with the chemical tests stipulated in various pharmacopeias if unused herbal remedies are available. However, difficulties arise if the herbal medicines concerned have been processed, for example, in powder form or as decoction (often with other ingredients); most, if not all, of the morphological characteristics will be lost and the

Table 2 Selected pesticide metabolites/residues found in biological specimens

Pesticides	Metabolites
<i>Organophosphorous</i>	
Malathion	Dimethyldithiophosphoric acid (DMDTP) and dimethylthiophosphoric acid (DMTP)
Parathion	Diethylthiophosphoric acid (DETP), diethylphosphoric acid (DEP), and <i>p</i> -nitrophenol
Diazinon	Diethylthiophosphoric acid (DETP) and diethylphosphoric acid (DEP)
Chlorpyrifos	3,5,6-trichloro-2-pyridinol
<i>Carbamates</i>	
Carbofuran	Carbofuran phenol and 3-ketocarbofuran
Carbaryl	α -Naphthol
<i>Organochlorines</i>	
Aldrin/dieldrin	Dieldrin
Chlordane/heptachlor	Nonachlor and oxychlordane

Figure 1 (a) An extraneous herb containing tropane alkaloids isolated from (b) a batch of *Rhizoma Atractylodis*.

Figure 2 Appearance of (a) *Aristolochia fangchi* (guang fanji) and (b) *Stephania tetrandra* (han fanji).

Figure 3 Appearance of (a) *Flos Daturae Metelis* and (b) *Flos Campsis*.

chemical tests documented in pharmacopeias may no longer be applicable. In this case, to assist in devising suitable toxicological analyses in relevant biological specimens obtained from the patient(s), the analyses of the toxic ingredients associated with the confused herbs or suspected herbs by chromatographic-based techniques are usually the method of choice. It would be prudent for toxicologists to have a better understanding of the types of toxic herbs, which may be region specific, and are likely to cause poisoning. Table 4 lists some toxic ingredients of toxic herbs relevant to forensic toxicology.

Adulteration

Inferior products or extraneous materials

Many medicinal herbs are sold by weight. Therefore, direct or intentional adulteration with other inferior products or extraneous materials is often found. A noted example is soaking

Cordyceps sinensis, a precious herbal medicine, in concentrated lead solution in order to increase its weight and increase earnings.

Conventional medications

The purpose of intentional adulteration of conventional medication(s) into herbal medicines is to disguise the belief that the use of such 'natural' products can exert the claimed effects on improving health. However, incidents of toxicological concern due to intake of herbal remedies with undeclared conventional medications continue. A study in Taiwan revealed that 24% of 2609 market samples of TCM analyzed were found to have been adulterated with synthetic drugs of various pharmacological activities. One of the commonly encountered examples is the adulteration of phosphodiesterase type-5 inhibitors such as sildenafil and vardenafil (Western drugs for treatment of male erectile dysfunction) in sexual enhancement health

Table 3 Incidents reported to be related to mix-up or misidentification of herbs

Nontoxic herbs	Toxic herbs (toxic ingredients) involved	Reasons for mix-up or misidentification	Consequences
<i>Stephania tetrandra</i>	<i>Aristolochia fangchi</i> (aristolochic acid)	Similar appearance and common name	Patients developed nephropathy and some required kidney transplants
<i>Solanum Lyratum</i>	<i>Aristolochia mollissima</i> Hance (aristolochic acid)	Same common Chinese name 'Pak Mo Tang'	Patient presented with kidney failure and cancer of the urinary tract
<i>Mussaenda pubescens</i>	<i>Gelsemium elegans</i> (gelsemine)	Similarity in appearance	Patients developed dizziness, generalized weakness, and even unconsciousness
<i>Flos Campsis</i>	<i>Flos Daturae Metelis</i> (tropane alkaloids)	Similarity in appearance	A number of anticholinergic poisonings
<i>Radix Gentianae</i>	<i>Radix or Rhizoma Podophylli emodis</i> (podophyllotoxin)	Similarity in appearance	Patients developed gastrointestinal symptoms followed by severe encephalopathy
<i>Polygala Chinensis</i>	<i>Stephania rotunda</i> (L-tetrahydropalmatine)	Proprietary medicine containing undeclared toxic herb	It caused life-threatening effect on central nervous system and respiratory depression in children and liver damage in adults

Table 4 Toxic ingredients of some common herbs relevant to forensic toxicology

Toxic alkaloids/ingredients	Scientific name	Common name
Aconitum alkaloids: aconitine, mesaconitine, and hyaconitine	<i>Aconitum napellus</i> <i>Aconitum carmichaeli</i> <i>Aconitum kusnezoffii</i>	Monkshood 'Chuan wu' Wolfsbane, 'Cao wu'
Scopolamine, atropine, hyoscyamine	<i>Datura metel</i> <i>Datura stramonium</i> <i>Hyoscyamus niger</i> <i>Atropa belladonna</i>	'Yang jin hua' Jamestown weed Henbane Deadly nightshade
Gelsemine	<i>Gelsemium elegans</i> <i>Gelsemium sempervirens</i>	'Gou wen' Carolina jasmine
Coniine	<i>Conium maculatum</i>	Poison hemlock
Harmine, harmaline	<i>Banisteriopsis caapi</i>	Caapi
Strychnine	<i>Strychnos nux-vomica</i>	'Maqianzi,' Nux vomica, Ignatia
Matrine and oxymatrine	<i>Sophora tonkinensis</i>	Vietnamese Sophora
Aristolochic acids	<i>Aristolochia fangchi</i> <i>Aristolochia clematitis</i> <i>Aristolochia reticulata</i>	'Fang ji' Birthwort Red River snake root
Podophyllotoxin	<i>Podophyllum emodi</i> <i>Podophyllum peltatum</i>	'Guijiu,' wild mandrake Mayapple
Attractyliside and carboxyatractyliside	<i>Atractylis gummifera</i> <i>Callilepis laureola</i> <i>Xanthium sibiricum</i>	Chamaelon, birdlime Impila 'Cang er zi'

products. In addition, there was an increasing trend for the use of analogs of drugs in virility products. These analogs are mimic chemicals of the original drugs by modifying their molecular structures to varying degrees. Unlike conventional medicines, drug analogs do not usually have proper safety evaluations and clinical study data, and are likely to pose a significant threat to health. Examples of analogs of sildenafil that had been found in herbal preparation are shown in **Figure 4**.

As adulterated ingredients are not declared in their packages with respect to identity and quantity, it may result in serious

intoxications due to drug interactions and overdose. For instance, an outbreak of hypoglycemia in 68 patients resulted in three fatalities in Hong Kong. Sildenafil and glibenclamide were detected in the urine. Subsequent investigations confirmed that some of the patients have consumed sexual enhancement health products containing these undeclared drugs.

Another commonly encountered example is the adulteration of synthetic drugs in herbal slimming formulae. The drugs involved are anorexics (e.g., amfepramone, fenproporex, sibutramine, fenfluramine, phentermine), anxiolytics (e.g., diazepam, clonazepam), and antidepressants (e.g., fluoxetine).

Figure 4 Chemical structures of sildenafil and analogs of sildenafil: (a) sildenafil, (b) hydroxyhomosildenafil, and (c) acetildenafil.

Table 5 Common detection methods for contaminants/adulterants in biological specimens and herbal products

Contaminants/adulterants	Examples of common toxic ingredients	Sample preparation	Common detection methods
Heavy metals	Arsenic, lead, mercury	Digestion using mineral acid such as concentrated nitric acid	AES, atomic absorption spectrophotometry (AAS), ICP-AES, or ICP-MS
Pesticides	Organophosphorus, carbamates	Mixing with acetylthiocholine (AcTC) and Ellman reagent, (dithionitrobenzoic acid)	Screening of Organophosphorus and carbamates by measuring cholinesterase activity in blood
	Organophosphorus, carbamates, organochlorines, pyrethroids	Liquid–liquid extraction or solid phase extraction	GC-ECD, GC-NPD, GC-MS, or LC-MS
Toxic herbs	Aconitine Atropine Scopolamine Gelsemine Podophyllotoxin Tetrahydropalmatine Aristolochic acid	Liquid–liquid extraction or solid phase extraction	GC-MS or LC-MS
Conventional medications	Sibutramine Fenfluramine Glibenclamide Sildenafil, tadalafil, vardenafil and analogs Phenolphthalein Spironolactone Dexamethasone phenylbutazone Piroxicam	Liquid–liquid extraction or solid phase extraction	GC-MS or LC-MS

AAS, atomic absorption spectrophotometry; ECD, electron capture detection; NPD, nitrogen phosphorus detection.

This problem is widespread, and occurs in many countries such as Hong Kong, Germany, and Brazil.

Analytical Strategy

As it is virtually impossible to screen for all toxic substances in every case, a rational case-specific analysis may be necessary. The presence of characteristic features of remnants and the symptoms exhibited by the patient may provide clues to the type of poisoning. Strategy for sampling and subsequently devising appropriate analytical methods for a case should be made with reference to background history of the case, clinical or pathological features presented, and/or specific requests made by the relevant parties such as medical officers, pathologists, and/or the police. Herbal residues and/or herb samples, empty containers and/or packaging inserts suspected to have been taken by the person should be collected as analysis of these items may be valuable for determining the types of

analyses required on the biological specimens to substantiate the cause of poisoning.

For all suspected cases, the biological specimens usually available for analysis include blood/serum and urine. In the case of chronic exposure, additional specimens such as fingernails or hair may be useful. As the growth rate of hair is $\sim 0.6\text{--}1.4\text{ cm month}^{-1}$, hair provides a longer window of detection up to weeks or months. Other useful specimens such as stomach contents or vomit, if available, should also be taken. In postmortem cases, sections of liver or kidney are sometimes needed. Many toxic substances and their metabolites are present in liver at higher concentrations than that in blood. Consequently, liver may also be used to supplement the blood concentration data, in particular when it is the only specimen available in cases of advanced putrefaction. Kidney is sometime useful in the investigation of heavy metal poisoning.

Table 5 summarizes the analytical methodology generally used for detection of some common contaminants/adulterants for their main toxic ingredients in biological specimens and herbal materials.

Figure 5 An example of a scheme for screening of contaminants/adulterants in biological specimens.

An example of an analytical scheme used for screening of contaminants/adulterants in biological specimens is shown in [Figure 5](#).

Heavy Metal Analysis

There are various instrumental methods such as electrochemical, atomic absorption, and flame emission spectrophotometry, inductively coupled plasma (ICP) coupled with either atomic emission spectroscopy (ICP-AES) or mass

spectrometry (ICP-MS) to analyze metals in biological specimens. An advantage of both ICP-AES and ICP-MS is that they can screen simultaneously many metals as well as conduct selective quantification of a single element at a very low detection limit. Digestion of the biological specimens can be achieved simply with a concentrated mineral acid such as nitric acid. The use of ICP-MS instrument equipped with either a double focusing sector for high-resolution application or a collision cell capable of removing polyatomic interference in the presence of a significant amount of matrix can further

enhance its sensitivity and selectivity. As such, a much faster and simpler sample preparation which involves a simple dilution of body fluid with buffer consisting of a solution of Triton X-100, ethylenediaminetetraacetic acid, and ammonium hydroxide can be considered. Accuracy can further be enhanced by isotope dilution method as stable isotopes are available for most of the toxic metals.

Pesticide Analysis

In the analysis of pesticides in biological specimens, a combination of direct and indirect methods can be considered. For instance, if organophosphorus or carbamate pesticide poisoning is suspected, the cholinesterase activity of blood could be determined as the test can be conducted quickly.

Screening of blood cholinesterase activity

Organophosphorus and carbamate pesticides are well-known cholinesterase inhibitors. These pesticides inhibit the blood enzymes erythrocyte acetylcholinesterase (AChE), and the degree of enzyme inhibition is proportional to the amount of exposure such that AChE activities can be determined using a colorimetric method. The blood test is more effective for organophosphate exposure than for carbamate exposure because the enzyme levels due to carbamate exposure may return to baseline levels within hours. Each person has a different normal baseline value of cholinesterase; therefore, due care should be exercised in the interpretation of results.

Chromatographic techniques

Depending on the chemical/physical properties of pesticides and/or their metabolites, a combination of suitably selected extraction methods involving liquid–liquid extraction using, for instance, hexane/acetonitrile under neutral or acidic condition and solid phase extraction such as C₁₈ cartridges for sample preparation can be used. As some major metabolites of many pesticides are in forms of sulfate and glucuronide conjugates, enzymatic hydrolysis can be used prior to extraction to further improve the sensitivity.

Chromatographic techniques such as gas chromatography (GC) or liquid chromatography (LC) connected with various detectors can be employed to detect a wide range of pesticides with similar extraction properties, polarity, and detection characteristics. GC connected with specific detectors such as electron capture detector is particularly sensitive to organochlorine pesticides, while nitrogen phosphorus detector is sensitive for detection of organophosphorus pesticides. Low levels of pesticides both in herbal medicines and in biological specimens can also be analyzed using GC-MS. In addition to the retention time given by the corresponding GC techniques employed, the mass spectrometric detector allows sensitive detection (ppm to ppb) of a wide range of pesticides with structural information for confirmation purpose. As many pesticides are polar and thermally labile, derivatization such as methylation by diazomethane in methanol or acetylation using acetic anhydride in pyridine prior to GC analysis can increase the volatility and hence thermal stability for those pesticides that are not easily detected by GC. The additional mass gain by derivatization also improves the specificity of the mass spectral information.

Pesticides can also be analyzed using liquid chromatography-diode array detection (LC-DAD). The drawbacks of LC-DAD are the low chromatographic resolution compared with GC, and the low sensitivity of UV detection such that larger sample size, particularly in biological specimens, or derivatization may often be required. With the advancement of ultra-performance liquid chromatography (UPLC) using columns with sub-2 μ particles for higher separation efficiency coupled with triple quadrupole mass spectrometer, methods can be readily developed for sensitive detection of a wide range of pesticides and related metabolites in various matrices.

Analysis of Toxic Herbs and Conventional Medications

As the contaminants/adulterants of poisonous alkaloids and conventional medicines can be very diverse and unpredictable, making it difficult to generate a comprehensive list that are relevant to toxicological analysis, the analytical detection of poisoning from unknown sources can be a challenge to toxicologists.

In the detection of drug analogs in herbal medications, because of the lack of structural information, reference spectrum, and reference standard of an analyte involved, a more fundamental approach would be necessary. Discovery of herbal preparation adulterated with drug analogs often involved detection of subtherapeutic amounts of drugs with unknown spots or peaks by thin-layer chromatography or LC-DAD. Further investigation is then carried out by preparative chromatography to isolate the suspected active ingredient. The structures can be confirmed by techniques like tandem mass spectrometry (MS/MS) and two-dimensional nuclear magnetic resonance spectroscopy. Other methods, such as setting up of a comprehensive scheduled selected reaction monitoring (SRM) built from the most probable ion fragment, precursor ion scanning of common ion fragment and accurate mass Fourier transform ion cyclotron resonance mass spectrometry, can also be considered in the detection of analogs. The information obtained would be useful for devising or setting up methods for the toxicological screening of relevant drugs/metabolites in biological specimens.

While the majority of reported incidents in the context of contaminations/adulterations are confined to a limited number of toxic herbs and conventional medications, it is practical to devise specific multianalyte procedures to cover as many relevant analytes as possible based on available circumstantial information. Many well-known conventional drugs and some alkaloids found in toxic herbs can be covered by general unknown screening (GUS) procedures for screening of a wide spectrum of acidic, neutral, and basic organic drugs or poisons. As such, it is possible to incorporate those analytes that are compatible with the routine GUS procedures. For instance, toxic herbs with naturally occurring alkaloids are usually basic in nature and can be extracted by a carbonate buffer (pH 9) followed by extraction with a dichloromethane/toluene/isobutyl alcohol (3:6:1) mixture, which could also be used in routine GUS. Examples of alkaloids in the basic fraction include aconitum alkaloids (such as aconitine, mesaconitine, hyaconitine, and yunaconitine), gelsemine, atropine/scopolamine, tetrahydropalmatine, and beberine. In addition, the same basic fraction can also be used for the analysis of

conventional medications such as glibenclamide, hypnotics and sedatives, benzodiazepines, antihistamines, appetite suppressants (e.g., sibutramine, fenfluramine), and drugs for treatment of erectile dysfunction (e.g., sildenafil, vardenafil, and tadalafil).

Similar to the analysis of pesticides, GC and high-performance liquid chromatography (HPLC)/UPLC, coupled with various detectors are common instrumentations for screening of a wide range of organic toxic substances in biological specimens. Using a combination of mass spectrometry with either GC or HPLC/UPLC, confirmation and quantification can be simplified into one single analysis. GC-MS has been used for years in GUS for drugs and poisons with well-established techniques and many useful spectral libraries relevant to toxicological screening are available. However, GC is not suitable for direct analysis of polar compounds although derivatization can partly solve the problem. With the use of multianalyte analytical protocol to cover over hundreds or even thousands of drugs and poisons, the use of LC-MS gained popularity in many toxicology laboratories to provide fast, selective, and sensitive method for GUS of organic drugs and poisons. In addition, the use of triple quadrupole LC-MS/MS with preset SRM could screen for as many relevant toxic ingredients/markers as possible even without any diagnostic information of a case. The time-of-flight or orbitrap mass spectrometry coupled with LC or UPLC has provided another approach for comprehensive drug screening that provides a relatively high mass accuracy with resolution. Identification of drugs/metabolites is based on their accurate mass and confirmation could be achieved by comparison of retention time if a reference material is available and via drug metabolite patterns.

Behavioral Toxicology

D Gerostamoulos, Monash University, Southbank, VIC, Australia

© 2013 Elsevier Ltd. All rights reserved.

The ability of drugs, both prescription and illicit drugs, to cause behavioral changes is arguably one of the most common issues confronting forensic practitioners. The consumption of new designer drugs as well as combinations of alcohol and prescription drugs can lead to behavioral changes in persons, often resulting in violent crime. Victims of crime can also be subject to the effects of drugs through either covert or overt administration of substances in recreational or domestic settings. Sudden or unexpected behavioral changes resulting from the consumption of drugs can lead to adverse events, which include self-harm and death. Indeed, the risk of death, including homicide and suicide, is well documented with the use of alcohol, illicit drugs, and some prescription drugs. These dangers are confined not only to individuals using drugs themselves but also to those people living with drug-using persons but who themselves do not abuse alcohol or drugs (e.g., children).

Drugs of most concern include alcohol, all of the amphetamine class of drugs (including a range of designer stimulants, e.g., methcathinones), cocaine, benzodiazepines and related sedatives (e.g., zolpidem), and hallucinogens such as ketamine and phencyclidine (PCP), although many other illicit and prescription drugs can have profound behavioral effects directly or can modify the behavioral effects of other drugs. Newer drugs such as gammahydroxybutyrate (GHB) and other similar depressant drugs are often used in drug-facilitated sexual assault, rendering a victim incapacitated or unconscious.

Prevalence of drugs capable of causing behavioral changes is significant. Among the victims of homicide, the most common is alcohol, followed by benzodiazepines, cannabis, opiates, and stimulant drugs. This article explores the notion of behavioral toxicity and its relevance to forensic medicine and also provides some of the most common examples to illustrate the significance of this phenomenon.

What Is Behavioral Toxicity?

This is a term used to define changes in behavior that impact adversely on rational thought and actions that may predispose to violence or other behaviors and have been caused by the effects of chemical substances. Most typically, these substances are illicit drugs, but this can also be caused by the inhalation of volatile substances (e.g., petroleum products, solvents, etc.), the use of natural products that contain psychoactive compounds, or the misuse of prescribed medications. The net effect of these behaviors is often the association with criminal acts.

This phenomenon is illustrated by excessive alcohol consumption, in which a person becomes disinhibited, leading to an outburst of aggression following an argument, resulting in harm to another person. While the actions cannot be blamed on the drug itself, the drug has modified the person's behavior to increase the propensity to violence and often also the severity of the violence. This is a well-known association with excessive

alcohol use; however, with some drugs (e.g., benzodiazepines), changes in behavior are not so predictable and can depend upon frequency and dose as well as other factors.

Mechanisms of Action

Chemical substances may act on receptors in the brain or bind to membranes affecting cellular functions in the brain, modifying normal nerve function. The transmission of signals by nerves involves the use of chemicals known as neurotransmitters. These neurotransmitters include substances such as norepinephrine (noradrenaline), serotonin (5-hydroxy tryptamine or 5-HT), dopamine, *N*-methyl-D-aspartic acid (NMDA), and gamma-aminobutyric acid (GABA).

Interference in the actions of neurotransmitters can occur either by blocking the effects of these substances on receptors located on adjacent tissue (postsynaptic sites) or the nerve ending itself (presynaptic sites) or by modifying the release, reuptake, or metabolism of these substances. For example, cocaine inhibits the reuptake of norepinephrine and dopamine and thereby effectively prolongs the effects of released neurotransmitters. Reuptake is essentially a process to recycle neurotransmitters in which active processes exist within nerve terminals to reabsorb the released neurotransmitter. Amphetamines can increase the amount of neurotransmitter released by the nerve ending, thereby increasing the actions of the nerve impulse.

Benzodiazepines block the effects of released GABA. The binding of benzodiazepine on this receptor has a net effect of increasing the movement of chloride through ion channels in membranes. This process reduces the stimulation of areas in the brain involved in regulating a range of behaviors and physiological functions, including those involving emotions and memory.

Some drugs increase the actions of the neurotransmitter by inhibiting the enzyme responsible for metabolizing excess neurotransmitter, monoamine oxidase (e.g., the antidepressants moclobemide, phenylzine, etc.).

Alcohol

Alcohol, or more accurately termed as ethanol, is by far the most common drug affecting behavior. Alcohol is a complex drug in terms of its mechanism of action. It is a central nervous system (CNS) depressant and acts to depress various functions in the brain and nervous systems generally. It resembles the volatile anesthetics such as chloroform, ether, and the modern halogenated anesthetics. Alcohol not only affects membrane function nonspecifically but also affects a number of excitatory and inhibitory amino acid transmitters such as GABA, glutamate, dopamine, and serotonin (5-HT).

Blood ethanol concentrations (BAC) in excess of 0.02% adversely affect coordination skills and cognitive function.

These symptoms become quite obvious at BAC of 0.1%, causing slurred speech, unsteadiness on the feet, poor judgment, and decision making. Disinhibition is most apparent over 0.1% BAC and is associated with aggression and with loud and outrageous behavior, risk taking, and criminal activity. A high proportion of homicide cases (more than one-third) involve alcohol often at blood concentrations greater than 0.1%. In drug-facilitated crime cases, alcohol is the most common drug involved typically at blood concentrations of 0.10–0.15%, rendering a person incapable of responding to normal stimuli.

Stimulants (Amphetamines and Cocaine)

This group of strong stimulants typically includes (dex) amphetamine, methamphetamine, and the designer amphetamines such as 3,4-methylenedioxy-methamphetamine (ecstasy, (MDMA)), 3,4-methylenedioxyamphetamine (eve, (MDA)), *N*-methyl-benzodioxazolyl-butanamine (MBDB), and *p*-methoxy-amphetamine (PMA). They all act as strong stimulants of the CNS, and depending on the drug, elevate heart rate, increase anxiety, improve mood, and reduce the effects of fatigue. Ecstasy and some of the other designer amphetamines increase empathy and are often used in nightclubs to increase socialization. Owing to the stimulatory effects of these drugs on the CNS, persons become agitated and talkative. Other behavioral manifestations of strong stimulants include rapid or confused speech and aggressive behavior. The term 'excited delirium' has been used to describe symptoms of bizarre and/or aggressive behavior, shouting, paranoia, violence toward others, unexpected physical strength, and hyperthermia. This agitated behavioral state is more likely to be observed in persons abusing cocaine, engaged in repeated binge use of the drug.

Newer designer stimulant drugs, such as cathinones and methcathinones (e.g., mephedrone, methdrone), and their derivatives have become increasingly popular largely because of having similar behavioral properties as amphetamine. Even though not as potent as the traditional amphetamines, these derivatives have the potential to induce feelings of irritability, restlessness, and lack of concentration – important observations particularly in motor vehicle accidents.

Persons driving cars or motorcycles using these stimulants display less vigilance and are less able to properly respond to multiple inputs (i.e., display impaired divided attention tasks). These drivers are also likely to drift out of the lane of travel, show erratic driving, and are associated with high-speed collisions. Prolonged use of amphetamines and cocaine can cause long-lasting or even permanent damage to dopamine- and serotonin-containing nerves in the brain, leading to stereotyped behaviors and psychoses. Consequently, it should be of no surprise that these drugs are associated with violence, particularly assault, occasioning harm including homicides.

Anabolic Steroids

Anabolic steroids are the drugs related to the male sex hormone testosterone and have androgenic activity, or an ability to increase muscle mass and tone. Numerous drugs are available in this group, mostly illicit, as solutions for injection,

although some are taken orally. These steroids include stanozolol, nandrolone, methenolone, metandienone, oxymetholone, and tenbolone to name but a few. These drugs can be taken as small doses of two or more steroids, larger doses in cycles lasting 1–3 months, or as ever increasing doses as demanded. The net effect is a larger buildup of muscle mass compared to a drug-free situation for a given amount of body building.

A well-recognized side effect associated with the use of anabolic steroids is the appearance of mood disorders, irritability, and aggression. Controlled studies in athletes show a significant number of steroid users reporting major mood disorders, including mania, hypomania, and major depression. Psychoses, delusions, aggressive, and violent behavior are also strongly associated with active steroid users. Reports of fits of anger, assault, and attempted murder are also linked to steroid use.

Personality profiles of men using anabolic steroids also show enhanced physical and verbal aggression and disinhibition.

Hallucinogens

Hallucinogens produce an altered perception of reality and include lysergic acid diethylamide (LSD), often sold as 'trips' or 'tabs.' LSD users are often confused and exhibit illogical actions and may result in bizarre behaviors and paranoid delusions. PCP and its analogues, thienyl cyclohexyl piperidine (TCP), phenyl cyclohexylpyrrolidine (PHP), phenyl cyclopentyl piperidine (PCPP), and cyclohexamine (PCE), produce an altered conscious state leading to hallucinations, dysphoria, symptoms of dissociation, and distortion of visual and other sensory signals. PCP shows some actions similar to LSD. Ketamine shares similar properties with PCP and is used widely by veterinary surgeons. PCP is sold as powder, flakes, or liquid. In any of these forms, it can be impregnated in tobacco or cannabis cigarettes, or leaf material. Street doses of PCP range from 1 to 10 mg. Ketamine is sold as solutions for injection, powder, or tablet form. Ketamine is also commonly cut with other illicit drugs such as amphetamine, cocaine, and heroin.

Users of PCP can experience acute psychotic episodes leading to reckless and dangerous actions and it is not surprising that this drug is also associated with violence and dissociated behavior. In some persons, excessive PCP can lead to lethargy/stupor, acute brain syndrome, or even coma; however, surprisingly, many can be alert and oriented. Other common hallucinogens include plant alkaloid mescaline and active ingredient in 'magic mushrooms' psilocin/psilocybin. These substances produce physiological and psychological changes including anxiety, compulsive movements, and antisocial behavior (see Poisons: Detection of Naturally Occurring Poisons).

Benzodiazepines

Benzodiazepines are a large class of minor tranquilizers that are legally available, but are abused either by themselves or in combination with other drugs, often alcohol, amphetamines, and heroin. They include alprazolam, clonazepam, diazepam, flunitrazepam, and temazepam. The drugs sedate and reduce

anxiety, and in sufficient doses, produce unsteady gait, slurred speech, and disorientation. They often affect retention of events when under the influence of the drugs, for example, cause anterograde amnesia. Benzodiazepines have adverse effects on driving skills through impairment of psychomotor and cognitive skills such as increased reaction times, poor lane control and poor lane tracking, and impaired divided attention tasks. In some subjects, disinhibition may be observed with the excessive use of the drug either alone or in combination with other CNS active drugs. Alcohol is a commonly associated drug that intensifies these behavioral changes. Disinhibition of normal control mechanisms results in aggression and bizarre behavioral changes. These reactions, although not common, can produce disturbing changes when benzodiazepines are abused. In extreme cases, subjects may not have any conscious control over their actions (see Benzodiazepines).

Cannabis

Cannabis is the fourth most common recreational drug used around the world behind caffeine, alcohol, and nicotine. The psychoactive component of cannabis, delta-9-tetrahydrocannabinol (THC), is responsible for the majority of the drugs' effects. The most pronounced behavioral impairments include disruption of memory, particularly impairment of attention as well as distortions of perception and judgment. Psychomotor impairment for the duration of intoxication includes impairment of muscle control, manual dexterity, simple and complex reaction time, and performance of divided attention tasks. A high proportion of unexpected deaths involve the use of cannabis (e.g., suicides, homicides, and motor vehicle accidents). The detrimental effects of the drug can result in poor judgment and slower responses, which may cause harm or death, particularly in motor vehicle drivers who are under the influence of cannabis.

Psychoses

Aggression can occur even without the direct effects of drugs, particularly in psychiatrically disturbed persons. Several psychotic disorders, including schizophrenia, may be associated with symptoms of acute agitation and aggression. Cannabis intoxication can also cause acute psychotic episodes. Drug treatment can play an important role in the management of agitated persons. For example, short-acting antipsychotic medications can be used for the treatment of agitation and aggressive behavior of patients experiencing an acute psychotic phase. Benzodiazepines including clonazepam or lorazepam are also often given by injection to achieve rapid results.

Tolerance and Withdrawal

Users of essentially all of the drugs aforementioned will exhibit tolerance or neuroadaptation if the drugs are used regularly.

This applies particularly to the amphetamines and cocaine, although users of cannabis and other CNS depressants can show significant signs of drug dependence and tolerance if the drugs are constantly being misused. Chronic use of alcohol will also lead to dependence and tolerance. Tolerance occurs as the human body becomes accustomed to the pharmacological and physiological effects of the drug, causing drug users to compensate by consuming larger amounts of drug. They will consume doses severalfold higher during their active phase than when they first started using the drug. Tolerance can occur after days to weeks of use. Drug-dependent persons will, by definition, not only exhibit drug-seeking behavior but also show signs of withdrawal following drug abstinence. Withdrawal symptoms can often be more profound than the direct effects of drug. For strong stimulants, abstinence symptoms are often severe and will be associated with behavioral changes. This includes fatigue (hypersomnolence or rebound fatigue following excessive stimulation of the CNS), depression, and suicidal behavior. Paranoid psychoses and other mood disorders can occur and can be particularly troublesome.

Glossary

Accumulation Progressive increase in concentration following repeated doses of a drug.

Acidosis A blood pH value below 7.4.

Adipose tissue Body tissue containing stored fat.

Alkalosis A blood pH value above 7.4.

Antemortem Done or occurring before death.

Arterial Of or being in an artery (blood vessel carrying blood high in oxygen content).

Autopsy Examination of a corpse to determine or confirm the cause of death.

Biochemical conversion Structural change of a drug involving chemical processes occurring in living organisms.

Cell membrane The outer covering of cells.

Cholinesterase An enzyme that catalyzes the hydrolytic cleavage of the acyl group from various esters of choline and some related compounds.

Dalton Atomic mass unit.

Diffusion Movement of drugs along a concentration gradient.

Dissociation constant Equilibrium constant for the reaction in which a weak acid is in equilibrium with its corresponding base in aqueous solution.

Embalming To treat a corpse or a part of it with preservatives such as formaldehyde so as to prevent decay.

Enzyme induction Increase of drug metabolism by drugs or chemicals.

Enzyme inhibition Decrease of drug metabolism by drugs or chemicals.

Equilibration Development or maintenance of equilibrium.

Eschweiler–Clarke reaction Chemical reaction whereby an amine is methylated (reductive amination).

Excretion Physical removal of a substance (drug) from the body.

Extraction efficiency Ratio of the detector response of an analyte from an extracted sample to the detector response of the analyte from an unextracted sample (solution) containing the same amount of analyte that was added to the extracted sample.

Formulation A medicinal preparation used in a special form such as a tablet.

Glucuronidase An enzyme that catalyzes the hydrolysis of various glucuronides.

Hemolytic Destruction of red blood cells leading to the release of hemoglobin.

Heterocyclic ring Cyclic compound which has atoms of at least two different elements.

Homogenization To make, for example, a tissue specimen uniform in consistency.

Hydrolysis Reaction of a substance with water in order to be changed into one or more other substances.

Immunoassay A laboratory technique that makes use of the binding between an antigen and its homologous antibody in order to identify (and quantify) drug classes or – less often – a single substance.

Interaction The action of one drug to the effectiveness or toxicity of another one.

Interference Errors in the analytical results of chemical, physical, instrumental, but also of human origin.

Lipid solubility Ability of a compound to dissolve in fat or nonpolar lipids.

Media A fluid or tissue in which a substance is present or can be analyzed from.

Metabolism Enzymatic or biochemical transformation of a substance (drug) to metabolic products.

Methanolysis Reaction of a substance with methanol in order to be changed into one or more other substances.

Methylation Addition of a methyl group to a molecule.

Organophosphorous Organic compounds containing carbon–phosphorus bonds.

Oxidation Gain of oxygen and/or loss of electrons.

pH value Logarithm of the reciprocal of hydrogen ion concentration.

Physicochemical Relating to both physical and chemical properties.

Propellant A compressed gas that acts as a vehicle for discharging the contents of an aerosol container.

Rate-limiting step The slowest step in a metabolic pathway or series of chemical reactions which determines the overall rate of the other reactions in the pathway.

Redistribution (postmortem) Process of drugs diffusing from tissues into blood along a concentration gradient between death and time of specimen collection.

Reduction Loss of oxygen and/or gain of electrons.

Stability-indicating assay Validated analytical procedure that accurately and precisely measures active ingredients – drug substance or metabolite – free from potential interferences like degradation products, components from the particular matrix, or other potential impurities.

Sulfatase Enzyme that catalyzes the hydrolytic cleavage of inorganic sulfate from sulfate esters.

Therapeutic range Range of concentrations in blood at which a drug is effective with minimal toxicity to most individuals.

Transport mechanisms Mechanisms that enable cells to move materials into or out of a cell.

Trauma, traumatic An injury to living tissue.

Venous Of or being in a vein (blood vessel carrying blood low in oxygen content).

Vitreous humor Clear gelatinous substance that fills the eyeball.

Introduction

The question that is usually asked if a death case is suspected of poisoning is: "Did a drug cause or contribute to the death?" Although the answer is likely to come from combined analysis of the medical history, the circumstances surrounding death, the manner of death, and the measured concentration of the respective drug, the answer may not be straightforward or, in some cases, remain uncertain. Even if extensive background information is available, there are many uncertainties relating a concentration found postmortem to the concentration before death, and from the putative antemortem level to the severity of poisoning.

A major difficulty which has to be dealt with in a post-mortem toxicology investigation is artificial changes related to the media, the drug, and its concentration; such artifacts are not naturally present in the corpse but can occur already during the process of dying, pretreatment of the corpse (such as embalming), the postmortem time period, as well as the collection, storage, processing, and analysis of postmortem specimens. Artifacts may produce qualitative as well as quantitative changes. These artifacts remaining an inherent part of post-mortem toxicology, it is essential to be aware of them and to be able to identify situations where this occurs.

This article gives a short summary on artifacts that can occur during the pre-final phase and the period until the autopsy is performed, including changes that may occur in the quality of the specimens and the amount of drugs present, and those artifacts caused by the analytical procedure.

The Pre-Final Phase

In any drug-related case, it is necessary to state whether a drug concentration in blood is compatible with overdose or is more in accord with therapeutic use. Pharmacokinetic concepts describing the time course of drug absorption, distribution, metabolism, and excretion can provide an estimate of the

quantitative relationship between the dose of a drug and the observed blood or tissue concentration. Although an accurate measurement of the blood concentration can be accomplished in most cases, the interpretation of the analytical result is not straightforward.

For example, a considerable overlap occurs in the concentrations seen in clozapine-, morphine-, or methadone-related deaths following deliberate self-poisoning and in subjects who had died with no evidence of drug misuse. Factors likely to contribute to the uncertainty of published reference ranges for drugs prior to death are summarized in Table 1.

The rate and extent of a drug's absorption is largely dependent on its physicochemical properties, the formulation, and the physiologic factors. Blood flow is the rate-limiting step in drug distribution. Accordingly, rapid distribution of lipid-soluble drugs is observed between the blood and lungs, liver, heart, and brain. Less rapid equilibration is found in skeletal muscle, bone, and adipose tissue, which receive a smaller volume of blood per unit mass per minute. Drugs with a molecular mass of up to 600 Da quickly diffuse out of the vascular system into the interstitial fluid bathing the cells. Lipid-soluble molecules penetrate the cell membrane itself while water-soluble molecules such as pregabalin are dependent on special transport mechanisms. The more lipophilic the compound, the faster is its distribution into tissues. In acute poisoning cases, death can occur before steady state has been reached, resulting in appreciably higher arterial than venous blood concentrations. For example, maximum arterial plasma concentrations of amitriptyline, heroin, 6-acetylmorphine, and morphine were 4, 2.4, 5.4, and 1.4 times higher, respectively, than maximum venous concentrations during the absorption/distribution phase.

Drug metabolism, which refers to the biochemical conversion of a drug to another chemical form, can be considerably altered by induction or inhibition of enzyme activities. There is clear evidence that smoking cessation increases blood concentrations of drugs such as warfarin, olanzapine, or clozapine, which also have narrow therapeutic concentration range. Smoking cessation causes smoking-induced CYP1A2 levels to

Table 1 Factors likely to affect a drug's reference range already during the pre-final phase

<i>Antemortem influence</i>	<i>General remarks</i>	<i>Example(s)</i>
Changes of pharmacokinetic parameters	Immobilization; drop in blood pressure; decreased tissue perfusion and tissue hypoxia; impaired ventilation and acidosis; progressive dehydration; hepatic and renal failure; disease state	Respiratory depression due to accumulation of the active metabolite morphine-6-glucuronide in renal insufficiency or decreased clearance and lower volume of distribution of morphine in trauma and fire victims; about fourfold increase of the half-life of diazepam in alcoholic cirrhosis; inflammation increases drug penetration
Interactions	Pharmacokinetic and pharmacodynamic interactions: drug–drug, drug–alcohol, drug–nutrient, and drug–herb interactions	Golden seal – inhibition of CYP2D6; increase of the area under the curve for amitriptyline and nortriptyline in the presence of ethanol
Tolerance	Acquired tolerance due to decreased efficacy at the receptor site or increased metabolism due to induction of enzyme activities; cross-tolerance, for example, between opioids may also occur	Cocaine, heroin, methadone
Treatment in hospital	Intravenous fluids; resuscitation measures; devices, which automatically deliver medication by the parenteral route	Decreased or nondetectable amounts of alcohol and drugs; intubation-related lidocaine artifacts; locally elevated drug levels due to fentanyl patches

return to normal. Drug–drug interactions are widely recognized and are listed in databases and texts. Far less, however, is known on drug–nutrient or drug–herb interactions. Activities of CYP3A4, 2C9, and 1A2 may be increased by St. John's Wort, whereas inhibition of CYP3A4, 2D6, and 1A2 has been observed by kava. Drugs with the relative elimination rate being slower at higher than at lower concentrations in blood may also present a problem. For example, a 50% increase in the daily dose of aspirin has been observed to produce a 300% increase in salicylate in the blood. Moreover, plasma concentrations of gabapentin, methylenedioxymethamphetamine (Ecstasy), and propranolol do not increase proportionally with increasing dose.

Renal excretion playing a major role in drug elimination, considerable accumulation of drug metabolites can be observed in subjects suffering from renal insufficiency. Therefore, determination of active metabolites, such as morphine-6-glucuronide or oxypurinol, the active metabolite of allopurinol, is of utmost importance. Usually, a high ratio of parent drug to metabolite concentration has been taken as an indication that death had occurred rapidly, and vice versa. However, such ratios may be misleading as genetic factors contribute substantially to the large differences among people in metabolic clearance of drugs.

Besides these pharmacological considerations, the context in which the subject was found must be considered in interpreting analytical data. Acidosis or alkalosis can markedly alter the disposition of a drug. Acidosis produces a shift of weak bases, including most drugs, from the blood or extracellular fluid to the cellular space. These shifts occur in all tissues including the brain. Extended blood loss, for example, caused by traumatic bleeding, results in an increased heart rate, peripheral vasoconstriction, and transfer of extracellular fluid into the blood circulation. Therefore, the blood drug concentration in a trauma victim may differ from the concentration present at the time of trauma. In addition, treatment during hospitalization or resuscitation may produce artifacts (see Table 1).

There are many additional and unique aspects causing postmortem changes of the corpse, the sample, and the analyte therein, which will subsequently be discussed.

The Corpse

Postmortem changes affect the micro- and macroenvironment of the foreign substances and refer to all processes by which their movement between body fluids and tissues takes place. This phenomenon is gathered under the generic term of postmortem redistribution. Currently, there are no accepted biomarkers available to indicate the magnitude of postmortem changes likely to influence drug distribution in blood.

Decomposition of circulating proteins and membrane macromolecules that bind drugs, destruction of biological membranes that delineate drug compartments, loss of energy-dependent gradients and postmortem acidosis that influence the local concentration of drugs during the early postmortem period all contribute to changes postmortem.

Many drugs are sequestered antemortem in organs or may be still present in the gastrointestinal tract in acute poisoning; they can be redistributed either by the vascular pathway

depending on the fluidity of the blood, by passive diffusion through the blood vessels, or from the lumen of a body cavity toward surrounding organs. Inflammation may promote drug penetration into tissues. If a vomit containing a large amount of drug is aspirated into the trachea, postmortem diffusion into heart blood should be considered; examples of this are ethanol, toluene, and lidocaine. Although postmortem diffusion of a drug from the urinary bladder is rare, it can take place in the case of a large amount of urine containing a high content of drug. Therefore, femoral blood should not be used as a single specimen for drug analysis when the substance is a likely cause of death.

Tissue redistribution of drugs after death is determined by some of the same factors governing distribution (see earlier); it is more common for basic drugs and has largely been attributed to the physicochemical properties of a drug including molecular size, dissociation constant, lipid solubility, tissue binding, and the environmental pH value. Lipophilic drugs often have a high tissue concentration and are more likely to be redistributed. It appears that an apparent distribution volume $>3 \text{ l kg}^{-1}$ facilitates postmortem redistribution, such as for the antidepressant amitriptyline. The apparent distribution volume is simply a proportionality constant relating the plasma concentration to the total amount of drug in the body; in man, it can vary from 0.04 (plasma volume) to 20 l kg^{-1} or more. Atomoxetine may be an exception inasmuch as the drug apparently undergoes postmortem redistribution despite a relatively low distribution volume of 0.85 l kg^{-1} .

A longer period of time between death and sample collection may give more potential for postmortem changes. Nevertheless, the most important quantitative changes in drug concentration occur within a few hours following death. In animal studies, the concentration of dothiepin steadily increases to reach about 400% of the original concentration at 8 h postmortem. Fluctuating blood concentrations of fluoxetine and norfluoxetine in a dog model could be observed up to 2 h after the animals had been sacrificed with no significant differences between the 2-h and 12-h samples. However, the time period (e.g., up to 24 h) may not necessarily correlate with the ante/postmortem concentration ratios, and some drugs have lower postmortem levels than antemortem levels (e.g., phenobarbital, phenytoin, carbamazepine, and its 10,11 epoxide metabolite, as well as tetrahydrocannabinol).

Additional factors that have not been studied in detail but are likely to contribute to postmortem redistribution are (1) the position of the body when found, which may result in blood draining from central to peripheral sites if blood has remained sufficiently fluid, and (2) the storage temperature of the body, with a greater potential of changes at a higher temperature.

Body fluids, tissues, and drugs present in these specimens are subject to fundamental changes. Enzymes naturally present in the body cause autolysis, while putrefaction is due to destruction by microorganisms. The pH value in blood immediately drops up to 5.5 after death has occurred, and a decrease in water content can often be observed. Hemolysis is seen with most blood specimens, which can be either fluid, clotted, or partially clotted. In addition, hypostasis occurs due to gravity. Overall, the composition of the postmortem blood sample which is most commonly used to test for actual impairment

or acute overdose substantially differs from that taken from a living subject.

For any drug which exhibits an unequal distribution between the liquid and cellular components of blood, drug measurement may be influenced by the profound changes of the medium. Distribution ratio may differ not only between drugs but also between the parent drug and major metabolites. Ratios determined from spiked or authentic samples – the latter procedure should be favored over *in vitro* partition experiments – can be useful for a gross estimation, keeping in mind that the distribution range may scatter over a wider range in postmortem samples as has been shown for cannabinoids.

Parallel or opposed effects to that resulting from postmortem redistribution may arise from the formation of totally new entities, an artificial raise of the drug concentration, or degradation of labile compounds. A most prominent example is ethanol, which may be produced by a wide range of microorganisms penetrating from the intestines or from the skin as part of postmortem degenerative processes. Generally, postmortem produced levels may be lower than 0.07%, but may reach significant concentrations up to 0.22% if conditions are optimal. Formation of ethanol may be more pronounced after severe trauma and at an elevated temperature. If the body is kept refrigerated, no ethanol is usually produced within 24 h; however, its formation can occur if the body is not refrigerated within 4 h of death. It is important that determination of ethanol is corroborated by analyses from other fluids, such as vitreous humor, which is well protected from microbial infiltration after death.

Artificial formation has also been observed with gamma hydroxybutyrate (GHB), cyanide, and carbon monoxide. Fatalities mostly involved gamma butyrolactone and 1,4-butanediol, which are readily available precursors of GHB. In postmortem peripheral blood, endogenously formed GHB could reach 200 mg L⁻¹, which overlaps with those of reported fatalities. Although GHB cutoff values of 30 or 50 mg L⁻¹ blood or analysis of additional samples such as urine and vitreous humor have been proposed, appraisal of postmortem concentration is challenging. The amount of carbon monoxide in blood may increase due to postmortem formation by decomposition of hemoglobin and myoglobin during putrefaction, especially in cases of drowning. As smoking may be a common source of carbon monoxide hemoglobin, a cutoff value of 10% is useful.

A number of compounds are unstable in whole blood, such as all volatile compounds, *N*- and *S*-oxide metabolites, ester-type drugs, molecules with a nitro group, *N*-sulfate and *N*-glucuronide metabolites, acyl glucuronides, sulfhydryl-containing drugs, alkyl nitrites, and peroxides. Instability in postmortem fluids and tissues is largely due to chemical or metabolic instability. Cocaine and heroin are the most notable examples, which are broken down in an aqueous solution and enzymatically. The nitro benzodiazepines (e.g., flunitrazepam, clonazepam, and nitrazepam) are also known to degrade after death to the corresponding 7-amino form. Conversion of morphine glucuronides, which are stable in freshly drawn blood from living subjects, to morphine is attributed to residual or bacterial glucuronidase activities.

An embalming procedure can cause dilution of the blood, leading to a partial or complete loss of the drug present at the time of death. Embalming fluids contain formaldehyde, which

is a highly reactive chemical agent, and also alcohols including ethanol. Most likely pathways of drug changes are through hydrolysis or methylation via the Eschweiler–Clarke reaction depending on time, pH, and concentration of formaldehyde. For example, amitriptyline has been formed from nortriptyline, methamphetamine from amphetamine, and *N,N*-dimethylamphetamine from methamphetamine. Conversion of bupropion to the respective *N*-methyl derivative is more efficient than for olanzapine with its secondary amino group being embedded in the heterocyclic ring. Denaturation of body fluids and tissues may also render specimens more difficult to extract.

The Sample

Specimens that are routinely collected include blood from peripheral sites such as the femoral or subclavian veins as well as heart blood, urine, gastric contents, and organs, particularly liver. Further samples may be taken, depending on the case (see Table 2). Incorrect or insufficient sampling will severely affect a postmortem investigation. The nature and integrity of a sample submitted for analysis largely define the reliability and relevance of any analytical result. Although availability is often dictated by the case, selection of the sample is far more important than in other branches of forensic toxicology. In addition, the use of appropriate containers and preservatives can be critical for identifying a substance.

How samples should be collected from the corpse has not been detailed here but is described elsewhere. Some guidelines have been published for collecting the most appropriate specimens for analysis. Sampling should be standardized to minimize site-to-site variability and to ensure comparability of the analytical results. Contamination being the most common cause of artifacts, sampling should be performed before the autopsy is started, if appropriate.

Peripheral blood such as femoral blood is suggested to be subject to redistribution from muscle and fat only. Nevertheless, at least a specimen taken from another site should be analyzed for a proper interpretation of the blood concentration. In the case of ethanol, vitreous humor is an appropriate second specimen, and liver has been the most common second specimen for drug analysis. Liver may also be helpful to diagnose intoxication with an antidepressant; for example, the ratio of amitriptyline to nortriptyline concentrations has been suggested to differentiate acute intoxication from therapeutic use.

To analyze postmortem specimens will be useless if intoxication has been survived for a few hours or days in a hospital; samples collected during the stay should preferably be analyzed instead. Evidence collected at the scene such as drug paraphernalia or containers with remaining liquid or solid remains can provide additional information; such information may drive analysis forward in the right direction in some instances whereas in others, suspected substances may not be implicated in the fatality at all.

An appropriate and clean container has to be used for each sample to maintain its integrity. If a container is partially filled, evaporation of volatiles and oxidative loss of drugs may occur, whereas the container or the lid may break upon freezing if it is filled to a minimum headspace. The best material is glass,

Table 2 Samples that should be taken prior to autopsy or during autopsy, if appropriate

<i>Sample</i>	<i>Acquisition/Amount</i>	<i>Purpose</i>	<i>Challenge</i>
<i>Samples that should be taken prior to autopsy</i>			
Femoral venous blood; alternative: another peripheral specimen	By preparation and ligation of the blood vessel; 10–25 ml	Quantitative analysis	Insufficient amount, results may not be used in isolation; the specimen is not beyond postmortem redistribution
Urine	By puncture of the abdominal wall; up to 50 ml	Drug screening; exposure toward volatiles (e.g., metabolites of toluene, xylene)	Availability; no evidence of acute exposure; failure in very acute poisons or if a drug is not cleared by the kidneys
Liquor cerebrospinalis; vitreous humor	Suboccipital puncture/aspiration by suction; respective total volume	Biochemical markers such as glucose, lactate, urea, and nitrogen in suspected renal failure; ethanol	Small volume; there are different opinions whether specimens from both eyes may be combined
Hair, nails	Preferably from the posterior vertex, fixed by a string; a pen-sized bundle of hair; nail clippings as far as available	Long-term changes in pattern of drug use; noncompliance; discrimination between single or chronic exposure; exposure by a third party; crime under the influence of drugs; heavy metal poisoning	Hair soaked with body fluids or vomits; small database for the interpretation of results determined from nails
<i>Samples that can be taken during autopsy</i>			
Heart blood	After opening of the pericardial sack; up to 20 (50) ml	Drug screening	Subject to postmortem diffusion/ redistribution; not for quantification
Gastric contents or vomited material	Separation of tablets or suspected materials; total volume if inhomogeneous or 50 ml	Drug screening	Documentation of the total volume; inhomogeneous specimen; a small amount of drug present may not be assigned to oral intake, but does not rule out an overdose
Bile bladder fluid	Aspiration or squeezing into a container; total volume	Previous/chronic exposure	Rather chronic than acute use; concentrations may be significantly higher than in blood; highly variable blood/bile ratios
Tissue such as liver, muscle, kidneys, lungs, and brain	Sampling at an early stage of autopsy; ~50 g	Whenever body fluids are not available	Recording of organ weight; substantial site-to-site variability; liver: tissue from deep within the right lobe
Entomological species	As much as available	In case of putrefaction	Qualitative result; larvae rapidly eliminate drugs when removed from the corpse
Bone or bone marrow	3 cm of the long bones; or as much as available	In case of skeletonization or heavy metal poisoning	Qualitative result

which is recommended whenever solvent abuse or an anesthetic death is suspected. A teflon- or aluminum foil-lined lid should then be used. Disposable plastic tubes or bottles are appropriate provided that breakage upon freezing or adsorption of the drug does not occur. Plasticizers, particularly phthalates, may originate from plastic bags. Testing of the material before routinely collecting specimens will reduce sampling artifacts.

There is no obligatory requirement for specimen preservation, which affects blood specimens in particular. Generally, anticoagulants are not recommended. Formation of ethanol and degradation of cocaine may be slowed preserving the sample with fluoride. Nevertheless, *in vitro* formation of ethanol has been observed in samples containing fluoride. In cocaine-containing specimens, an accumulation of methyl ecgonine has been observed in the presence of fluoride. Therefore, summing up the concentrations of cocaine and its three hydrolysis products to estimate the cocaine concentration in blood at death has been suggested. Preservation with fluoride at a final concentration of 1–5% is also recommended for

analysis of cyanide, carbon monoxide, and GHB. It also stabilizes lorazepam and oxazepam by approximately 13% compared to unpreserved samples. However, fluoride should not be added when organophosphorous compounds are involved. Acidification may stabilize cocaine and *N*-glycosides; and ascorbic acid may reduce losses of substances such as apomorphine. Ascorbic acid, however, may lead to a reduction of *N*-oxides, resulting in an increase in the concentration of the parent drug, and chlorpromazine and clozapine can be cited as an example.

The Compound

Postmortem changes must be considered for all but a few drugs. Basically, instability of a drug substance depends on its structure, physicochemical properties, the matrix, the storage container, temperature, and time. Stability is defined as the capability of the sample material to retain the initial value of a measured quantity for a defined period within specific limits

when stored under defined conditions. Such consideration can inevitably not start until the time of sampling and covers the time until analysis. Some of the degradation mechanisms seen during storage are similar to those that have been observed during the postmortem interval (see earlier). Often, the particular matrix has not been considered, and stability of drugs in tissues has very rarely been reported.

Experimental investigation on time- and temperature-dependent changes may give information on the reaction type involved in drug degradation and on potential degradation products. It should be considered that postmortem degradation may differ from a drug's instability observed in biological fluids obtained from living subjects. For example, morphine is primarily affected by oxidation in freshly drawn blood, whereas in postmortem samples kept at the same conditions, hydrolysis of morphine glucuronides is the predominant reaction, the degradation rate being dependent on the particular glucuronidase activities of the specimen.

Sometimes, metabolites or breakdown products are far more stable than the parent compound. The poor stability of cocaine, benzoylecgonine, and methyl ecgonine, as well as of heroin and 6-acetylmorphine, is well documented. Alternate analysis for ecgonine and morphine as rather stable breakdown products is recommended. Ethyl glucuronide (EtG) has been suggested as a marker of antemortem ingestion of alcohol in cases where postmortem production of ethanol is questioned. EtG being unstable in blood, however, a negative result may also arise from degradation of the phase-II metabolite. As ethyl sulfate is more stable due to the lack of sulfatases in bacteria, its determination along with EtG has been recommended. The breakdown of many benzodiazepine-type compounds has been studied in more detail. Interestingly, the long-term stability of the benzodiazepines estazolam and alprazolam has been attributed to the triazolo rings in their structures which make these compounds more resistant to hydrolysis.

Approaches to maintain stability such as pH adjustment, addition of inhibitors, or antioxidants have already been addressed earlier. The storage of analytes in blood dried on filter paper is an upcoming technique to adequately stabilize labile compounds. A commonly encountered condition in the forensic laboratory is lowering of the temperature, which will decrease all changes occurring through neoformation, hydrolysis, oxidation or reduction, and enzyme activities. For example, the cholinesterase activity in blood almost does not decline 3 weeks after storage at room temperature. The highest enzyme activities are present in liver, but can also be found in other tissues such as the kidneys and the brain. As degradation takes place even at 4 °C, immediate freezing of specimens is recommended. The majority of analytes in blood is sufficiently stable when stored at -20 °C for about 12 months except 7-aminonitrazepam, tetrahydrocannabinol, and zopiclone, for example. Postmortem testing of inhalants, aerosol propellants such as propane and butane, fuels, chlorinated solvents, and amyl nitrite is difficult not only as a result of their volatility but also of their instability. A loss of up to 25% of blood toluene has been observed in sealed glass tubes stored at room temperature for 7 days. Hair samples, however, should be stored at room temperature protected from humidity and light to avoid drug loss. Methemoglobin levels rise as an apparent effect of

frozen storage, whereas storage at -80 °C is most desirable for a reliable determination of carbon monoxide in blood.

The Analytical Assay

Although the history of a sample appears to be most relevant to the production of artifacts, artifacts may also occur during the isolation and determination of a drug. Appropriate procedures in postmortem drug analysis have been sufficiently covered by recent reviews.

False positives are common with immunoassays, and interactions are not limited to matrix effects or the structural similarity of compounds. Insufficiency of some assays for high-potency benzodiazepines is well known, and a hydrolysis step prior to analysis may overcome this problem.

Often, a special pretreatment or homogenization according to the specimen's nature and/or a more sophisticated cleanup extraction of putrefied or embalmed materials is required for all forms of chromatography. The lack of suitability of routinely applied isolation methods may result in poor recovery and coextraction of interferences, leading to signal overlap and ion suppression or enhancement.

The chemical properties of a reagent used for sample preparation can give rise to chemical reactions of the solvent itself, an impurity, or a stabilizer that it may contain. For example, phosgene in chloroform reacts to form carbamate derivatives during extraction of tricyclic antidepressants; and formation of methochloride adducts is known for clozapine, olanzapine, and ofloxacin when treated with dichloromethane. Artifactual formation of 4-androsten-3,17-dione and androsterone from the internal standards [16,16,17-d₃]-testosterone and [16,16,17-d₃]-5 α -androstane-3 α ,17 β -diol through enzymatic oxidation of the 17 β -hydroxyl function to a 17-keto function by 17 β -hydroxysteroid dehydrogenase, and deuterium-hydrogen exchange at C16 during the methanolysis deconjugation step have been observed. Glucuronidase/arylsulfatase used for cleavage of phase-II metabolites has been suggested as a source of a cyclodipeptide which has been assigned as a possible dihydroergotamine artifact in a screening procedure.

As the extraction efficiency of a drug or metabolite from a postmortem specimen may vary depending on the sample matrix, validation of the analytical procedure is needed on all types of specimens. If it varies from case to case, or even from site to site within the same corpse, the standard addition method may be applied provided that a sufficient amount of specimen is available.

It is now recognized that determination of major or active metabolites and degradation products along with the parent drug is essential to avoid misinterpretation of the data due to artifacts. Such a stability-indicating assay is one that can accurately and selectively differentiate the intact drug from its potential decomposition products.

Conclusions

Each death is unique, and the factors that may alter the effects on and the concentration of a drug in the body are not known in detail in most cases. It must be accepted that artifacts as an

integral part of postmortem toxicology frequently interfere with a straightforward interpretation of the analytical results.

The conclusion that death was caused by intoxication should be based on three pillars: a concentration which is typically encountered in such fatalities, the history and the circumstances surrounding death must be consistent with poisoning, and exclusion of diseases or injuries that are inconsistent with life at the postmortem examination.

In addition, a thorough understanding of the kinetics and instability of a drug is imperative. Appropriate sampling techniques and measures to maintain the sample integrity will minimize further artifactual formation of both the analyte and the matrix following acquisition of the specimen. Investigation of samples taken from different sites may ease concerns related to postmortem redistribution. Analysis of tissue samples can be of value if a sufficiently large database exists. Often, a routinely applied analytical assay has to be modified; in this case, a thorough evaluation of the analytical procedure is mandatory. Application of a method that covers determination of the target analyte as well as its possible metabolites and degradation products will improve the informative value of such an assay.

Introduction

In most societies, alcohol (ethanol) is a legal drug used and abused for its mood-altering effects. It is a central nervous system depressant and as such inhibits many brain functions, leading to impairment of coordination, reaction time, and judgment. It also releases inhibitions by virtue of its depressant effect on inhibitory nerves. This may be at least partly responsible for the antisocial behavior displayed by many intoxicated people and may also be an important factor in criminal behavior.

In living subjects, the degree of alcohol-induced intoxication and performance impairment is best determined by mental and physical performance testing using a range of methods. Such testing is preferable to blood alcohol analysis because interindividual variations in tolerance to the effects of alcohol mean that different people will be impaired to different degrees at the same blood alcohol concentration. However, direct testing of impairment is reasonably time-consuming and often not practicable in a forensic context. It is not possible at all when the subject is deceased. Therefore, indirect methods such as blood and breath alcohol analysis have become the most common tools when assessing the degree of intoxication of living subjects. When dealing with the deceased, blood alcohol analysis is the best option.

In general, the alcohol-induced effects on human behavior are positively correlated with the blood alcohol concentration, and in most circumstances, the concentration of alcohol in blood taken from an arm vein will give a reasonable indication of the degree to which all organs and tissues of the body, including the brain, are exposed to alcohol. This follows from the fact that alcohol is very water soluble and distributes itself throughout the total body water. Blood is approximately 80% water and is an ideal vehicle for the transport of alcohol to all parts of the body.

Although blood from any part of the human circulatory system may be used for alcohol analysis, when dealing with living subjects, it is usually safest and most convenient to sample blood from an arm vein using a sterile hypodermic needle. Arteries are deeper and under higher pressure than veins so sampling of arterial blood is more likely to result in bruising and difficulty in stopping blood flow. If all that is required is a very small amount of blood (some analytical methods require only a few drops), the simplest approach is to use a sterile lancet to pierce a finger or thumb tip, allowing a few drops of blood to be squeezed from the minor puncture wound created.

Blood Collection

The most common method of collecting blood for alcohol analysis in a living person is by puncturing a cubital vein (near the surface of the arm on the inside of the elbow) with a hypodermic needle. The needle may be either attached to a syringe or double ended, with one end pushed through a rubber seal in an evacuated tube, once the vein has been pierced by the other end. Blood is drawn from the vein by virtue of the vacuum in the tube or by withdrawing the syringe plunger, thereby creating a partial vacuum in the syringe. Evacuated tubes are the method of choice where veins have good blood flow and are easily located. They have the advantage of allowing multiple tubes of blood to be collected from a single needlestick. However, where veins have weak blood flow and are prone to collapsing, an evacuated tube is usually not the best option. In this case, the standard syringe is more useful, allowing the operator (phlebotomist) to provide more gentle and variable suction when drawing blood from a 'difficult' vein.

The volume of blood collected by either method is usually about 5–10 ml. This is more than enough for the blood alcohol analysis, including repeat analyses, if required. Modern forensic toxicology laboratories should be able to perform a full alcohol analysis on 0.5–1 ml of blood.

In the deceased, a wider selection of sites for blood collection is available, but this is counterbalanced by potential difficulties in the interpretation of differences between alcohol concentrations in blood from different sampling sites. In general, such differences are likely to be small in living people. But major trauma and postmortem changes can lead to large differences. Blood of uncertain origin (e.g., vein, artery, heart, or other ruptured organs and tissues) may gather in the chest and mix with the interstitial fluid that bathes the organs of the chest. This mixed fluid is often all that is readily available to the pathologist dealing with a body essentially exsanguinated as a result of gross trauma. If this mixed fluid is submitted as a 'blood' sample for alcohol analysis, the analysis result will be difficult to interpret.

For example, if a person dies with a large amount of alcohol in their gastrointestinal tract, the difference between the alcohol concentration in blood from an arm vein and that in blood taken from the abdominal cavity may be very large if the abdominal cavity is contaminated with alcohol derived from a ruptured gut.

As for living people, venous blood taken from an arm or a leg of a deceased person, before significant decomposition starts, are the best samples for interpretative purposes. Such samples will best reflect the blood alcohol concentration at the time of death.

As in all other forensic work, collection of blood for alcohol analysis must involve steps to ensure the integrity and security of the sample, at least for the time necessary to transport it to the analytical laboratory and to perform the required analysis. This is particularly important when the result of the analysis is used to determine whether or not the sample donor was over or under a statutory blood alcohol limit.

In clinical settings, phlebotomists usually clean the skin at the sampling site with an alcoholic antiseptic solution, before blood sampling. Although swabs containing isopropanol are commonly used for this purpose, swabs containing ethanol are also available and their use has the potential to elevate the blood alcohol concentration if the alcohol on the skin is not allowed to completely evaporate before blood sampling. Clearly, the cleansing agent should not be ethanol based. Even isopropanol could interfere with the analysis if it is used as an internal standard in the analytical procedure (see the section 'Analysis') or if the analytical method cannot discriminate between ethanol and isopropanol.

Blood sampling without prior skin cleansing could potentially lead to contamination of the blood with a variety of microorganisms having the capacity to either produce or break down alcohol in the blood. But the risk of this occurring is effectively eliminated if the blood is drawn into evacuated tubes or placed in other clean receptacles containing sufficient preservative to inhibit microbial growth. An anticoagulant must also be used to maintain the blood in a liquid state. This facilitates the taking of homogeneous subsamples for analysis.

A wide range of evacuated blood sampling tubes exists for specific clinical purposes, but most of them are not suitable for

forensic blood alcohol analysis. Therefore, in most jurisdictions, the law enforcement agencies are required to use blood sampling kits specifically designed to allow a clean blood sample to be taken and stored in a manner that prevents clotting and any other deterioration that might affect the measured blood alcohol concentration. The contents of a generic blood specimen collecting kit are pictured in Figure 1. It is self-contained and requires no additional equipment that might be open to question in terms of its cleanliness and alcohol-free status. The evacuated tubes contain both preservative and anticoagulant in quantities sufficient to be effective when the tube is filled with blood. Potassium oxalate in combination with 1% sodium fluoride is the preferred additive to collection tubes to stop blood from clotting, to inhibit microbial growth and to maintain the stability of blood alcohol concentrations as much as possible. Refrigeration at approximately 4 °C is also recommended for prolonged storage, especially where ambient temperatures are high.

It is important to recognize that it is impossible to stabilize blood alcohol concentrations completely over long periods. Many studies have shown that in properly preserved and well-sealed blood samples, the blood alcohol concentration falls slowly over a period of weeks and months. The cause is not completely understood but is probably due mainly to slow chemical oxidation. The rate of loss is very variable but could amount to 1–2 mg per 100 ml month⁻¹ of refrigerated storage.

In many countries, whole blood is used for forensic alcohol analysis. In others, blood plasma or serum is used. In clinical laboratories, plasma or serum is often the material of choice for alcohol analysis because many other clinical tests are also performed on serum or plasma. This may seem a minor detail because serum and plasma are derived from and usually make up over 50% of whole blood. Nevertheless, the difference between the alcohol content of whole blood and that of serum or plasma is always significant. The alcohol content of all biological fluids is proportional to their water contents because alcohol is almost exclusively present in the water phase of these fluids. On the basis of the relative water content, the alcohol concentration in serum and plasma is approximately 11% higher on a weight per volume basis, than the

Figure 1 A generic blood specimen collection kit with two vacuum tubes (a,b), sterile needle (c), needle holder (d), nonalcoholic swab (e), seals (f), and packaging (g).

alcohol concentration in whole blood from which the serum and plasma was derived. When the plasma: blood alcohol concentration ratio has actually been measured, a range of values have been found, with the average being closer to 1.15 than to the theoretical value of 1.11.

Any conversion of plasma or serum alcohol concentrations to whole blood concentrations must take into account the natural variations in water contents of these fluids. This will introduce an additional element of uncertainty in the analytical result.

Analysis

Chemical

The first useful methods for forensic blood alcohol analysis were chemical methods involving oxidation of the alcohol by a strong oxidizing agent. The most well known of these methods was developed by Eric Widmark, a Swedish pioneer in the field of alcohol metabolism. His method involved incubating small blood samples suspended over an acid dichromate solution in a sealed container. During an incubation period of many hours, the alcohol evaporated from the blood and was absorbed and completely oxidized by the acid dichromate mixture. The more alcohol oxidized, the less dichromate was left at the end of the reaction. The analysis was completed by measuring the residual dichromate in solution. This was usually performed using another chemical oxidation–reduction reaction that could be easily followed by an obvious color change when the reaction was complete. Although this procedure was robust and generally reliable, it was cumbersome compared with modern analytical methods and was subject to error if other oxidizable volatiles were present in the blood. In other words, the method was not specific to ethanol. Other common alcohols such as methanol and isopropanol would give a response similar to that of ethanol.

Methanol and isopropanol are common industrial solvents with many properties similar to those of ethanol. They may be consumed deliberately as substitutes for ethanol, or accidentally as contaminants or additives in illicit alcohol products.

Chemical methods for alcohol analysis are especially prone to error, where postmortem blood samples from decomposing bodies are being analyzed. Microorganisms produce a wide range of volatile oxidizable compounds, some of which are regarded as very good biological markers of putrefaction. It is obviously desirable to have analytical methods able to distinguish these compounds from each other as well as from ethanol, which may also be a product of putrefaction.

Biochemical

An analytical method still widely used in clinical laboratories involves oxidation of alcohol using the enzyme alcohol dehydrogenase (ADH). Although still not completely specific for ethanol, this method is simpler and quicker than chemical methods. The enzyme-catalyzed oxidation of ethanol to acetaldehyde requires the coenzyme nicotinamide adenine dinucleotide (NAD). For every molecule of ethanol oxidized, one molecule of reduced NAD is produced. Reduced nicotinamide adenine dinucleotide (NADH) is readily measured in solution

by its absorption of ultraviolet light at a wavelength of 340 nm, using a relatively inexpensive spectrophotometer of the type used in some school laboratories. The degree of light absorption is directly proportional to the molecular concentration (molarity) of NADH, and this, in turn, is equivalent to the molecular concentration (molarity) of alcohol existing before the enzyme-catalyzed reaction started.

A number of variations of this method have been used and several commercial kits are available, either for small numbers of samples or for large numbers run using autoanalyzers of the type widely used in hospital laboratories.

Although such methods may still be used in forensic toxicology laboratories as screening methods, they are not adequate by themselves. ADH catalyzes the oxidation of a variety of alcohols in addition to ethanol. Therefore, there is no way of telling whether or not an apparent positive ethanol result is partly or even completely due to the presence of another alcohol such as methanol or isopropanol.

Gas Chromatography

The introduction of reliable gas chromatographs in the early 1950s significantly improved the forensic toxicologist's ability not only to distinguish ethanol from a variety of other low molecular weight volatile compounds but also to clearly distinguish between ethanol and other alcohols. This led to gas chromatography (GC) being the current method of choice for alcohol analysis in modern forensic toxicology laboratories.

In comparison with many other modern instrumental techniques, the GC is relatively inexpensive, simple, fast, and robust and provides the accuracy and precision necessary for reliable quantitative analysis.

A representation of the different components of a gas chromatograph is shown in [Figure 2](#). The sample to be analyzed is injected into a heated injector port, where it is vaporized and carried by a stream of gas into a coiled tube (called a column) located in a thermostatted oven. The column is commonly made of metal or glass. It is either packed with a porous absorbent material or coated with a film of absorbent material on its inner surface. Modern GC columns are typically of the latter type and are many meters long, up to about 0.5 mm in diameter and made of very pure glass (fused silica) reinforced by an outer coating of tough plastic material.

The film of absorbent material is responsible for separating individual volatile components of the sample, as it passes through the column. The film will retain the volatile components to varying degrees depending on the degree of molecular interaction between the film and each component. The degree and speed of separation of the components can be optimized by careful selection of the type of gas, gas flow rate, column temperature, column geometry, and the chemical nature of the absorbent film. A complete separation of common alcohols such as ethanol, methanol, and isopropanol can be commonly achieved in less than 2 min using a 20–30 m column.

As the different components emerge from the end of the column, they may be detected using a variety of different methods including mass spectrometry. However, most forensic toxicology laboratories find the common flame ionization detector (FID) more than adequate for blood alcohol analyses. These detectors are simple and very reliable. As the individual

Figure 2 Schematic diagram of a gas chromatograph.

volatile components pass through a small flame, they are ionized, allowing them to be detected in the form of an analog electrical signal. The size of the signal is dependent on the amount of the detected component. This signal is then digitized to allow for easy quantitation.

The magnitude of the detector signal, by itself, is insufficient to determine the alcohol concentration of a sample. However, by comparing this signal with that produced by a sample of known alcohol concentration, the alcohol concentration of the unknown sample can be easily calculated because the detector response is directly proportional to the alcohol concentration. This, of course, is only true if the known and unknown samples are treated in exactly the same way before and during the analysis.

Although this is simple and robust methodology, its accuracy and precision can be affected by variations in the volume of sample injected onto the GC column. Consequently, a more reliable method designed to maximize accuracy and precision is almost always employed. This involves the use of internal standardization, a widely used technique in analytical chemistry. It improves accuracy and precision and provides a powerful diagnostic tool if things go wrong with the analytical system. If an internal standard is used, the chances of a system failure going unnoticed are very low.

Internal standardization commonly involves diluting all blood samples and calibration standards with a fixed volume of a liquid containing another volatile compound that is readily detected by the analytical system, does not naturally occur in blood samples in readily detectable concentrations, and has a retention time clearly different from that of alcohol. Examples of such compounds are *n*-propanol and *t*-butanol, both volatile members of the alcohol family. If either of these internal standards is used and the analytical method is working well, the GC detector will produce, for every sample, a signal for the internal standard, which will be essentially the same size for every sample. Unusual variations in the internal standard signal could indicate poor precision of sample injection volume or poor control of the temperature of the GC column.

However, some variation in these parameters is inevitable, even with the best methods, using the best equipment. And without an internal standard, this would lead to variation in analytical results. Much of this variation is eliminated if calculation of the analytical results is based on the ratio of the alcohol signal to the internal standard signal. Precision of results is improved because variations in the alcohol signal are largely canceled by corresponding variations in the internal standard signal.

Figure 3 shows an automatic diluter used to take a fixed volume of blood and a fixed volume of an internal standard solution and dispense them into a sample container; in this case, a headspace vial used in headspace GC. The blood: internal standard dilution ratio is commonly about 1:10, producing a solution that is much less viscous than whole blood and one that may be injected directly into the injection port of the GC. Although the diluted sample can be manually injected, this is labor intensive and has largely been replaced with automatic injectors. These are usually integrated with the gas chromatograph and extract small volumes of the diluted blood samples and inject them into the injector port of the GC at regular intervals.

Regardless of whether manual or automatic injection is used, the direct injection of diluted blood samples into the injector port tends to shorten the life of GC columns and necessitates frequent cleaning of the injector port. As a result, a cleaner method of introducing samples into the injector port is often preferred. Headspace injection is such a method and involves analysis of the air (headspace) in equilibrium with the diluted blood sample. In many ways, it is analogous to breath testing, whereby the blood alcohol level is determined by analysis of air in equilibrium with blood perfusing the lung tissue.

Reliable analysis using headspace GC requires the diluted samples to be incubated in sealed vials with large headspace volumes at controlled temperatures. The incubation period is usually chosen to allow full equilibration of alcohol and the internal standard between the diluted sample and the

Figure 3 Apparatus for automatic sampling of blood (a) and automatic dispensing of the blood into a headspace sampling vial (b). An internal standard solution is mixed with the blood in step (b).

Figure 4 A headspace-gas chromatograph complete with automatic headspace sampler. The sampler is fixed to the top of the gas chromatograph and includes a rack of headspace vials awaiting analysis.

headspace air. **Figure 4** shows a typical computer-controlled headspace GC system. In this apparatus, the sample vials sit in a rack on top of the GC before incubation and are each incubated for 12.5 min at 60 °C in a thermostatted shaker to the left of the sample rack, before analysis. All instrumental parameters such as column temperature, total analysis time, sample incubation temperature and time, gas flow rate, injector port temperature, and detector temperature are controlled by the

Figure 5 FID #1. Column: DB Wax $\times$ 0.32 mm $\times$ 10 m, 0.5 μ m film; joined to DB-1 0.32 mm $\times$ 20 m, 5.0 μ m film. 1, Methanol; 2, acetone; 3, ethanol; 4, isopropanol; 5, *n*-propanol (internal standard).

computer. This system, in common with many others, has two analytical columns housed in the same oven. Each is connected to the same injection port but is connected to its own detector. This allows for two independent analyses to be performed simultaneously on columns having different selectivity. The columns are always chosen so that if any compound cannot be fully separated from ethanol on one column, it will be separated from ethanol on the other. **Figures 5** and **6** show representative detector outputs (chromatograms) demonstrating complete separation of a mixture of five different volatile compounds, including ethanol and the internal standard

Figure 6 FID #2. Column: DB-1 0.32 mm $\times$ 30 m, 5.0 μ m film. 1, Methanol; 2, ethanol; 3, acetone; 4, isopropanol; 5, *n*-propanol (internal standard).

n-propanol. Each compound appears as a peak in the chromatogram and is identified by the time it takes to pass through the GC column. This is called the retention time, indicated for each compound at the top of each chromatogram. The compounds are quantitated on the basis of the size of their peak areas relative to known standards, using internal standardization as previously described.

Quality Assurance

Any laboratory conducting forensic alcohol analysis should have a documented quality management system involving both quality assurance and quality control. Quality assurance involves maintenance and compliance with documented processes and procedures aimed at ensuring that the laboratory's output is fit for purpose. Quality control involves regular checking of the laboratory's output to demonstrate that it is fit for the purpose.

It is not necessary for all laboratories to conform to identical quality standards, as long as the standards are well defined and available to the laboratory's customers. However, there are many advantages in following internationally accepted quality standards. Standards such as ISO/IEC 17025:2005 have been written by experts in their field and provide solid guidelines for quality assurance in chemical testing laboratories, recognizing that there are often many satisfactory ways of complying with a standard.

In a blood alcohol testing laboratory, quality assurance measures will include proper validation of all analytical methods used in the laboratory, thorough documentation

and dissemination of the laboratory's procedures and processes, maintenance of appropriate training programs for both technical and administrative staff, regular audits of the laboratory's quality system, and regular participation in inter-laboratory collaborative trials and proficiency tests. It is common for laboratories to seek accreditation by a national or international body, accreditation being granted when the laboratory demonstrates that it complies with an international standard such as ISO/IEC 17025:2005.

Validation of a new method is easily achieved by comparing results obtained using the new method with those obtained using a previously validated method. If there is no statistical difference between methods in terms of results obtained, the new method is considered validated. If there is no previously validated method available, validation is usually performed by rigorous testing of the new method with standards having the same range of alcohol content and composition as the samples for which the method is being developed. Such testing should involve determination of accuracy, precision, and specificity over the relevant concentration range and should involve several analysts on several different days, ideally using several analytical instruments.

It is common to perform blood alcohol analysis using large batches of 25–50 samples, each sample being analyzed at least twice, with the average of replicate results being reported. Regardless of the quality of the method, this average result will always have some degree of uncertainty associated with it. Therefore, in many jurisdictions, an appropriate 'margin for error' is deducted from this result before reporting. This deduction should not be arbitrary. It should be based on the actual precision and accuracy of the method, determined during validation studies and updated when necessary.

It is usually not appropriate to specify rigid performance criteria for an analytical method used by different laboratories in different countries. The quality and type of analytical equipment and infrastructure required to run this equipment will often determine the accuracy and precision of results. Nevertheless, most modern GC methods should allow a blood alcohol concentration of 100 mg per 100 ml (0.1%, w/v) to be determined with a standard deviation (SD) of about ± 1 mg per 100 ml ($\pm 0.001\%$, w/v). If reliable calibration standards are used, the accuracy of modern methods should be very close to 100%. Therefore, the 'margin for error' to be applied to any result should be determined largely by the precision of the method and the number of replicate analyses. The margin for error in the average of duplicate results is typically not more than about 2% of this average. If referring to 'standard uncertainty' as defined in the ISO GUM, use of a coverage factor of ~ 2 will give a 95% confidence interval equivalent to the result of a single analysis ± 2 SD. But when multiple analyses are performed, the 95% confidence interval for the mean will be less than ± 2 SD.

In headspace GC methodology, calibration standards must be run in every batch to ensure a high degree of accuracy, and it is best practice to run additional quality control samples in each batch. These are samples of known concentration, usually made up to be close to relevant statutory limits or other important thresholds, for example, nonstatutory cutoff limits applied under workplace health and safety policies.

Each laboratory should set its own acceptance criteria for batches of samples and for the results of individual samples within those batches. These criteria will typically involve limits to the differences between replicate results for a particular blood sample; limits to how far results for quality control samples can deviate from the expected value; limits to the variation between internal standard peak areas, minimum standards for peak areas and peak symmetry; and limits to the variability of calibration factors. Once again, these criteria should not be arbitrary; they should reflect the actual characteristics of the method so will often vary between laboratories and may vary with time within laboratories.

Laboratories conducting forensic alcohol analysis should keep all documentation relating to the testing procedures for an appropriate time. This time is usually defined by statute and allows for all relevant evidence to be produced, if required, in any subsequent litigation. Furthermore, although the analysis of blood for alcohol content is a relatively simple procedure, and one which has become highly automated, the science behind it is not simple. Therefore, any laboratory engaged in forensic alcohol analysis should employ the services of at least one forensic scientist with appropriate expertise. Ideally, they should have broad knowledge of the laboratory's procedures relating to the receipt, identification, documentation, chain of custody, and secure storage for all blood samples and other items of evidence. They should also understand the behavior of alcohol in blood during long-term storage, the theory and

practice of alcohol analysis, and how to make appropriate allowance for uncertainty in analytical results. Knowledge of human alcohol metabolism and the effects of alcohol are also useful and often expected, when engaged in blood alcohol litigation.

Urine and Other Body Fluids

A Stowell, Environmental Science and Research Limited, Porirua, New Zealand

Introduction

In forensic science practice, a satisfactory blood sample is not always available for alcohol analysis. In cases of severe trauma, the body may be completely exsanguinated. Even if a body is intact, the blood may be decomposing as a result of microbial growth. Yeasts produce alcohol, and many bacteria produce alcohol or break it down, so the presence or absence of alcohol in the blood of a decomposing body may not be good evidence of antemortem alcohol consumption or sobriety. When looking for evidence of antemortem alcohol intake, the ability to perform alcohol analysis on a range of other body fluids and tissues can often assist in the interpretation of questionable blood alcohol results. In some cases, it may also allow reasonable estimates of blood alcohol concentrations when no blood is available for analysis.

Alcohol exists almost exclusively in the body water and just as blood has a high water content (~85% wt/vol or ~80% wt/wt), so do most of the body's soft tissues and organs, apart from those with a very high fat content. Therefore, once an alcohol dose has been fully distributed about the body by the blood, the concentration of alcohol in a soft tissue such as muscle, liver, brain, kidney, etc. will be proportional to the water content of that tissue. For example, if a tissue's water content is 10% higher than that of blood, the alcohol concentration of that tissue will usually be about 10% higher than that of blood. This is the basis for estimating blood alcohol concentrations from alcohol concentrations in other parts of the body.

An understanding of the processes of absorption, distribution, and elimination of alcohol is necessary when interpreting concentrations of alcohol in different parts of the body. These processes define the shape of the blood alcohol curve, or the change in a person's blood alcohol concentration with time.

The blood alcohol curve, examples of which are shown in **Figures 1–3**, consists of three phases. The first is the absorption phase, where the rate of absorption into the blood is faster than the combined rate of metabolism and distribution. In this phase, the blood alcohol concentration rises. The second phase is the distribution, equilibration, or 'plateau' phase, where absorption is coming to an end and is largely offset by the distribution of alcohol into the body water and removal of alcohol from the body by metabolism. The length of this phase is highly variable, as is the shape of the blood alcohol curve during this phase. At one extreme, this phase is represented by a sharp peak and at the other by an essentially horizontal line. The third and final phase is the elimination or 'clearance' phase, where absorption and distribution are complete and the only factors influencing the blood alcohol concentration are metabolism and excretion. In this phase, the blood alcohol concentration is falling at an essentially constant rate until it reaches about 20 mg/100 ml. At this point, the rate of loss of

alcohol from the blood changes from zero order to first order. In other words, the rate of loss becomes concentration dependent (exponential rate of loss).

Absorption

Absorption refers to the process by which alcohol passes from the gastrointestinal tract into the blood. Alcohol begins to move into the bloodstream within minutes of entering the stomach, but absorption of alcohol into the blood directly from the stomach is relatively slow. The stomach lining is not well adapted for absorption. It is adapted more for containment, to allow food to be homogenized and partly digested before delivery into the small intestine. The small intestine has a very thin wall and a large surface area compared to that of the stomach. It is well supplied with blood and is specifically adapted for nutrient absorption. It is in the small intestine where most absorption of alcohol takes place. Only in circumstances where release of stomach contents into the small intestine is unusually delayed will the rate of absorption of alcohol directly from the stomach exceed the rate of absorption of alcohol from the intestine.

A valve called the pyloric sphincter separates the stomach from the small intestine. When this valve is closed, the stomach contents are blocked from reaching the small intestine. When it opens, the stomach contents flow into the small intestine, where further digestion and absorption takes place. Alcohol requires no digestion and is absorbed very rapidly without any expenditure of energy, flowing passively across the intestinal wall down a concentration gradient.

Therefore, the rate of absorption of alcohol into the blood mainly depends on how fast it travels through the stomach into the small intestine, a process called gastric emptying. The rate of gastric emptying is governed by many factors. Food in the stomach will generally slow it down. The alcoholic strength of a beverage can also influence gastric emptying, with strong spirits able to irritate the stomach, leading to closure of the pyloric sphincter and a delay in alcohol absorption. In some circumstances, the irritation can lead to prolonged closure of the sphincter, resulting in vomiting. This is a useful protective mechanism, where a dangerously high dose of alcohol has been consumed.

Prediction of alcohol absorption rates is very difficult. A single dose of alcohol can be almost fully absorbed and transported into the blood in less than half an hour or it may take more than 2 h.

Following identical doses of alcohol, rapid absorption of alcohol into the blood will lead to a higher maximum or peak blood alcohol concentration than will occur following slow absorption. Metabolism of alcohol begins as soon as alcohol enters the blood, and the longer it takes for full absorption to occur, the more alcohol is metabolized before the absorption is complete.

Figure 1 Alcohol absorption/elimination curve showing overshoot peak.

Rapid absorption of alcohol can sometimes lead to a sharp 'spike' in the blood alcohol concentration, as illustrated in **Figure 1**. This is not common and only occurs when the rate of absorption of alcohol into the blood is much faster than the rate at which alcohol diffuses out of the blood into the body water. It is most likely to occur when drinking on an empty stomach and is unlikely to occur when drinking after or during a meal. When drinking occurs in a stepwise manner, the absorption phase of the blood alcohol curve can also rise in a stepwise manner, as shown in **Figure 2**.

Differences between alcohol concentrations in different parts of the body are greatest during the early stages of alcohol absorption. Once absorption is complete and the alcohol dose is relatively evenly distributed throughout the total body water, these differences are usually quite small for tissues and organs having a good blood supply. For example, during the first few minutes of drinking on an empty stomach, the alcohol concentration in the blood draining the small intestine will almost certainly be rising rapidly. At the same time, there will be essentially no alcohol in the urine and no alcohol in the venous blood returning from the arms and legs. The blood draining the small intestine quickly flows to the liver and then to the heart. From the heart, it will first pass into the lungs and then travel back to the heart to be pumped to all organs. Therefore, there is a clear order in which different parts of the body are exposed to the first 'rush' of alcohol. The breath alcohol concentration closely reflects the alcohol concentration in lung tissue, which in the early stages of alcohol absorption will be higher than that in an arm or leg vein.

Distribution

The total blood volume is circulated in about 1 min; therefore, distribution of alcohol into the total body water is also quite rapid in spite of its large volume. The total body water volume is approximately nine times the volume of water in the blood, but a bolus dose of alcohol administered intravenously is fully

Figure 2 Alcohol absorption/elimination curve showing top-up peaks. Arrows indicate times at which alcoholic drinks were taken.

distributed into the total body water in about half an hour. Alcohol moves freely from the blood into the extracellular and intracellular water, exposing cells of all tissues and organs to a concentration of alcohol similar to that existing in blood. This also applies to unborn children who are exposed to the maternal blood alcohol concentration.

However, it is important to recognize that with few exceptions, body fluids that are easily sampled for the purposes of alcohol analysis, either ante- or postmortem, are held in isolated compartments, for example, the urinary bladder (urine), gall bladder (bile), and the eye (vitreous and aqueous humor). The alcohol in the fluids within these compartments does not exchange rapidly with alcohol in the blood. Therefore, the alcohol content of urine, bile, and vitreous and aqueous humor always lags behind the alcohol content of blood.

Elimination

Elimination refers to the processes of metabolism and excretion. Metabolism is the transformation of alcohol to nontoxic breakdown products (mainly water and carbon dioxide). Metabolism occurs mainly in the liver and also in the kidneys and to a minor extent in other organs such as the stomach. Metabolism is mediated mainly by a family of enzymes called alcohol dehydrogenases that convert alcohol to acetaldehyde, a very toxic compound. Aldehyde dehydrogenases then rapidly convert this to acetate, which is much less toxic. The acetate is broken down into carbon dioxide and water in a complex sequence of enzyme-catalyzed reactions. A number of other pathways for alcohol metabolism exist, but they appear to be minor, including those leading to glucuronidation or sulfation of the alcohol molecule.

The rate of alcohol metabolism depends to a large extent on the dietary status. A 20–30% increase in the rate of metabolism may be seen when drinking occurs after a meal, compared with drinking after an overnight fast. But regardless of dietary status, alcohol doses consumed during social drinking sessions are usually more than enough to overload the capacity of the body to metabolize alcohol. This means that the body will metabolize alcohol at an essentially constant rate representing the

maximum rate under any given circumstances. This rate will vary from person to person and from day to day for each individual, being dependent on a range of factors, including timing of food consumption before drinking and the degree of induction of the main enzyme systems responsible for alcohol metabolism. Metabolism rates are often expressed in terms of changes in the blood alcohol concentration per hour, during the elimination phase of the blood alcohol curve. For most healthy people who are not heavy drinkers, these rates are likely to be within the range of 10–20 mg per 100 ml per hour, but they could be considerably higher in heavy drinkers who have developed metabolic tolerance.

Excretion processes remove alcohol from the body in an unchanged state. The main excretion process involves removal of alcohol from the blood in the kidneys, via urine formation. But excretion of alcohol also occurs via the breath, perspiration, and any other process leading to removal of water from the body. Excretion usually accounts for less than 10% of the alcohol removed from the body, with the remainder removed by metabolism. However, when the blood alcohol concentration is very high, the proportion of alcohol removed by excretion increases because the alcohol contents of urine, breath, and sweat increase in direct proportion to the blood alcohol concentration. There is no such proportionate increase in the rate of alcohol metabolism.

Analysis of Urine and Other Body Fluids for Alcohol

It is usually appropriate to use the same methods employed for blood alcohol analysis when analyzing urine and other body fluids for alcohol content. A combined homogenization and dilution step will make sampling and analysis easier if the fluid is viscous or tissue is being analyzed.

With the exception of urine, oral fluid, sweat, and tears, the body fluids and tissues discussed in this article would only be taken from deceased persons for forensic alcohol analysis.

Urine

Because of its ease of collection and the volume usually available, urine is often sampled for forensic alcohol analysis. But as seen in Figure 3, at any point on the blood alcohol curve, the alcohol concentration in the urine is unlikely to closely reflect that in blood. In the absorption phase, the urine–blood alcohol concentration ratio is relatively low, while in the elimination phase, it is always much higher. Therefore, it is not surprising that this ratio has values ranging from close to zero to much greater than 10. It is not uncommon to find extremely high ratios in cases where alcohol is easily detected in the urine after being essentially eliminated from the blood. However, if urine sampling is carried out properly, it can be a useful indirect method of estimating the blood alcohol concentration.

The key to obtaining reliable blood alcohol estimates from analysis of urine is to first void the bladder, then void again as soon as practicable. Under these circumstances, the alcohol concentration in urine from the second void will reflect the average of the blood alcohol concentration over the period between voids. The shorter this period is, the closer the

Figure 3 Comparability of alcohol levels between body fluids. Reproduced from Karch SB (ed.) (1998) *Drug Abuse Handbook*, p. 340. Boca Raton, FL: CRC Press.

urine–blood alcohol concentration ratio will be to the ratio of the respective water contents of urine and blood, that is, between about 1.15 and 1.19. This range is appropriate if alcohol concentrations are expressed in terms of weight per volume, but where they are expressed in terms of weight per weight,

the average ratio will be close to 1.25. In the remainder of this article, all body fluid–blood alcohol concentration ratios are based on weight/volume measurements.

Division of the urine alcohol concentration by 1.3 is often used to estimate a blood alcohol concentration based on a urine analysis. If the time between voids is less than an hour and sampling occurs well after drinking stops, this approach will usually give a reasonable (and conservative) estimate of the blood alcohol concentration at the time of urine sampling.

When both blood and urine samples are available, the urine–blood alcohol concentration ratio may be used to determine the phase of the alcohol curve at the time of sampling. A ratio of less than 1 or not more than 1.2 strongly suggests that the subject was in the absorption phase. A ratio of more than 1.3 strongly suggests that the subject was postabsorptive at the time of sampling. This interpretation applies to living and deceased subjects, provided decomposition processes have not set in before blood or urine sampling.

Saliva/Oral Fluid

Measuring the alcohol content of saliva is an excellent means of estimating the blood alcohol concentration. Saliva alcohol concentrations closely parallel the blood alcohol concentration, as seen in [Figure 3](#).

The saliva–blood alcohol concentration ratio should be about 1.2 during the elimination phase of the alcohol curve, but in practice, it is much easier to obtain mixed oral fluid than pure saliva. Mixed oral fluid contains mucus secretions from the oral cavity in addition to saliva secreted from the parotid glands. The average oral fluid–blood alcohol concentration ratio is approximately 1.1, ranging from about 0.8 to 1.5, with surprisingly little dependence on either alcohol concentration or the phase of the blood alcohol curve.

Oral fluid is not commonly used for forensic alcohol analysis because of difficulties involved in obtaining substantial volumes and the possibility of contamination with high concentrations of alcohol after very recent drinking. Analysis of breath alcohol is much easier and serves the same purpose. However, satisfactory alcohol analysis can be performed with samples of less than 0.1 of a milliliter of oral fluid and residual alcohol resulting from recent drinking is usually completely cleared from the mouth within about 10 min by normal salivation and swallowing.

Vitreous Humor

Vitreous humor (VH) is a gel-like fluid obtained from the eye. Because it is in an isolated compartment well removed from the gut, putrefaction usually starts much later in the VH than it does in blood. Metabolism of alcohol in the VH is also minimal. For these reasons, the VH is often analyzed for alcohol when decomposition of the blood is suspected. If alcohol is found in VH, it may be used as evidence of antemortem alcohol consumption.

Approximately 2 ml of VH can usually be collected from each eye, providing enough material for alcohol analysis as well as for other drugs, if required. As for urine, the

VH–blood alcohol concentration ratio is variable and dependent on the phase of the blood alcohol curve, low values occurring during the absorption phase and higher values occurring during the elimination phase. The average VH–blood alcohol concentration ratio ranges from about 0.9 to 1.3, with individual values covering a much wider range. As with urine, this variation occurs because the alcohol concentration of VH lags behind that of blood. Therefore, it is not possible to accurately determine a blood alcohol concentration from a single VH alcohol concentration. But as with urine, a conservative estimate of the minimum blood alcohol concentration existing some time before death will be obtained if the alcohol concentration of the VH is divided by 1.3.

Cerebrospinal Fluid

Cerebrospinal fluid (CSF) provides cushioning for the brain and spinal column. Its volume in adults is about 125–150 ml and is continuously formed, circulated, and absorbed. It is not commonly sampled for alcohol analysis. In living subjects, it is sampled by lumbar puncture, a procedure requiring more skill and involving more risk than venous blood sampling. Even postmortem sampling of CSF is not common, as it is difficult to sample without contaminating it with blood. The CSF–blood alcohol concentration ratio lies within a range similar to that of the VH–blood ratio and is similarly dependent on the phase of the blood alcohol curve. But the minimum alcohol content of the blood sometime before death can be estimated from the CSF alcohol concentration in the manner described for the VH.

Synovial Fluid

Synovial fluid (SF) exists as a viscous lubricant in flexible joints such as the knee and elbow. If sourced from a knee, a sample of at least 0.5 ml may be obtained, that is, more than sufficient for alcohol analysis. The variability of the SF–blood alcohol concentration ratio may not be as great as that for urine, VH, or CSF, with the average SF–blood alcohol concentration ratio being close to 1. But in any individual case, the blood alcohol concentration could be between approximately half and twice the coexisting SF alcohol concentration.

As for urine, VH, and CSF, the SF–blood alcohol concentration ratio is dependent on the phase of the blood alcohol curve and the SF alcohol concentrations cannot be used to accurately predict blood alcohol concentrations, but they can be used to estimate the minimum blood alcohol concentration existing some time before death using the method described for VH and CSF.

Bile

Bile and blood have similar water contents, and bile is often collected during autopsies for the analysis of alcohol and other drugs. It is manufactured in the liver and stored in the gall bladder, which often remains intact and free of contamination in cases of violent death. But where death occurs in the

absorption phase, bile may be subject to contamination via postmortem diffusion of unabsorbed alcohol from the stomach. For autopsy specimens, values ranging from about 0.3 to 3 have been reported for the bile–blood alcohol concentration ratio, with an average close to 1. Division of the bile alcohol concentration by 1.1 should give a conservative estimate of the blood alcohol concentration some time before death.

Liver and Other Tissues

Liver, brain, kidney, and muscle tissues usually have water contents of 75–78%, so their alcohol contents *in vivo* should be a little less than the alcohol content of blood. The liver is a large organ and is easy to sample at autopsy, but it is not recommended for postmortem alcohol analysis. It is the main site of alcohol metabolism and although this stops very soon after death, the liver contains so much of the body's alcohol metabolizing 'machinery' (enzymes and relevant co-factors) that it only has to continue functioning for a short time to have a major effect on the alcohol concentration within the liver tissue. Furthermore, the liver is rapidly exposed to microorganisms from the gastrointestinal tract after death and contains glycogen stores that act as a source of glucose, an ideal substrate for fermentation by yeasts and bacteria. Therefore, the liver–blood alcohol concentration ratio varies greatly, ranging from about 0.3 to 0.9, with an average of about 0.6, even when sampling occurs before obvious putrefaction has begun.

Kidney tissue is not recommended as suitable for postmortem alcohol analysis because it also has as a high capacity for alcohol metabolism.

The alcohol content of brain tissue is reported to vary greatly from region to region, making it unsuitable for sampling for alcohol analysis. In a study using the frontal lobe as the source of brain tissue, the brain–blood alcohol concentration ratio averaged 0.86 and ranged from 0.64 to 1.2.

Skeletal muscle should be the best tissue to sample when attempting to estimate the blood alcohol concentration from analysis of human tissues. Very little alcohol metabolism occurs in skeletal muscle and large samples can be taken. The muscle–blood alcohol concentration ratio should be close to 0.86 and given the abundant blood supply to skeletal muscle, one might expect less variation in this ratio than is seen for body fluids in isolated compartments. However, significant variation is still seen, a range of 0.77–1.78 being found in one study, with the ratio dependent on the phase of the blood alcohol curve.

Bone marrow is well perfused with blood, is protected within the bone, and is well removed from potential contamination by either microorganisms or unabsorbed alcohol in the gastrointestinal tract. The variable fat content of marrow complicates alcohol analysis, but when the alcohol concentration of marrow tissue is normalized to a standard fat content, there appears to be a very strong correlation between the alcohol content of marrow and that of blood sampled at autopsy. However, this necessitates the analysis of marrow for its fat content. After such correction, the marrow–blood alcohol concentration ratio was found in one study to be within the approximate range of 0.6–1, averaging about 0.8 for human cadavers. The correction involved determining the fat content

of the marrow and recalculating the alcohol content for its aqueous phase only. This specimen will not be useful in decomposing cases because of the volatility of ethanol. Microbial growth will be a much more important factor in cases of (especially advanced) decomposition, than the volatility of alcohol. The stability of alcohol in enclosed, essentially aqueous compartments is remarkably high.

Sequestered Hematomas

Analysis of blood clots may yield evidence of alcohol intoxication at the time of a traumatic incident when such evidence cannot be obtained from the analysis of blood or other body fluids. For example, head trauma may cause blood clots. When many hours pass between the time of their formation and the time of death, metabolism will cause the blood alcohol concentration to fall and may result in no alcohol being detected in postmortem blood. Alcohol in blood clots is at least partly protected from metabolism. Therefore, alcohol in a clot may still be detectable well after the alcohol is completely removed from the general circulation. But it is not possible to estimate the blood alcohol concentration at the time of injury from the alcohol content of the clot. Clots take variable times to form, and there will be at least some movement of alcohol into and out of the clot, during and after formation.

Stomach Contents

By itself, the concentration of alcohol in the stomach cannot be used to predict blood alcohol concentrations, but it can help determine the phase of the blood alcohol curve. During the absorption phase, the alcohol concentration of stomach fluid is likely to be much higher than blood alcohol concentrations compatible with life, that is, above 500 mg/100 ml. In the elimination phase, stomach fluid will usually have an alcohol content lower than this. Knowledge of the phase of the alcohol curve will always be useful when interpreting alcohol concentrations in other body fluids, narrowing the possibilities for fluid–blood ratios.

Putrefactive Blisters

Putrefactive blisters form on the skin of decomposing bodies. These may be gas or fluid filled. The fluid is mainly water and easily sampled and analyzed for alcohol. Although there is some correlation between the alcohol content of this fluid and that of postmortem blood, there will always be some difficulty in determining how much of the measured alcohol in both fluids was present before death and how much was formed or destroyed by microbial action after death. The presence or absence of other putrefactive alcohols such as *n*-propanol, isopropanol, and *n*-butanol may give an indication as to whether or not significant changes in the ethanol concentration have occurred after death, but these indicators are not completely reliable in that their absence does not necessarily rule out postmortem ethanol production.

Sweat

Sweat is formed as required by the eccrine glands and has a water content of about 98%. Therefore, the sweat–blood alcohol concentration ratio should be approximately 1.15. This is essentially what is found, and there is a strong correlation between venous blood and sweat alcohol concentrations, with somewhat less variability in the sweat–blood ratio than is seen for body fluids in isolated body compartments. However, sampling of sweat for alcohol analysis is not very common because of difficulties in sampling and the need to take special precautions to avoid alcohol losses.

Tears

Tears come from the lachrymal gland and have water content close to 100%. There is a strong correlation between tear and blood alcohol concentrations in all phases of the blood alcohol curve, with the measured tear–blood alcohol concentration ratio ranging from 1.08 to 1.20. This suggests that alcohol in blood rapidly equilibrates with tear fluid. Therefore, tears

are close to an ideal medium for the estimation of coexisting blood alcohol concentrations. However, sampling will always pose ethical problems; an adequate supply of tears will not be forthcoming without some form of stress for the donor.

This article is a revision of the previous edition article by R.G. Gullberg, volume 1, pp. 86–93, © 2000, Elsevier Ltd.

Glossary

Gas chromatography (GC) A commonly used method in forensic toxicology for the separation, detection, and quantitation of the various components of a mixture of volatile substances. The separation is typically achieved by the use of a long narrow tube or column, in which the various components of the volatile mixture are sorted by their different affinities to the column.

Henry's law A physical law, which states that at equilibrium and at a fixed temperature there will be a fixed ratio between

the concentration of a volatile substance dissolved in a liquid and the concentration of the volatile in the air above the liquid.

Infrared (IR) Electromagnetic radiation that has a wavelength longer than that of visible red light and shorter than that of radio waves (i.e., between 0.7 and 1000 μm).

Lambert–Beer law A physical law, which shows that the intensity of light in an absorbing medium is related exponentially to path length and the absorption coefficient of the media.

Introduction

Breath alcohol (ethyl alcohol, ethanol) testing is one of the oldest and most established areas of forensic toxicology. It is employed by many countries as the sole analytical method to enforce drunk driving laws as there are many advantages of breath compared to blood alcohol testing. They include the following:

- Breath alcohol testing is noninvasive and safe. No needles are required as in the collection of blood samples, and hence there is no possibility of injury or transmission of disease.
- Breath alcohol results are known immediately compared to the several days or weeks for blood alcohol concentrations (BACs) to be reported by forensic laboratories. Hence the police are immediately aware of what charge to lay and whether medical treatment may be required for the arrested drunk driver (e.g., alcohol poisoning).
- Continuity (chain of custody) is relatively easy to ensure as the breath sample is provided by the drunk driver directly into the breath alcohol testing instrument. No special blood tubes, swabs, identity seals, biohazard refrigeration, or special transportation is required as it is for blood samples.
- No medical staff or phlebotomists are required for breath alcohol testing. Breath tests can be conducted by trained police operators, which shortens the time between the arrest and testing.
- There is no problem with the drunk driver's real or alleged phobia of blood or needles if he/she is being breath alcohol tested.

- Breath alcohol correlates better with brain alcohol concentration (arterial blood) and will give a better indication of alcohol-related impairment on the rising BAC phase compared to venous blood samples, which are the samples collected from drunk drivers.

The major disadvantage of breath alcohol testing is that breath testing can be conducted only in cooperative, conscious subjects, whereas blood samples may be collected in hospital from injured unconscious drivers.

This article covers the historical, biological, and analytical aspects of forensic breath alcohol testing, one of the tests most commonly conducted in forensic toxicology.

Historical Aspects

The history of forensic breath alcohol testing is shown in [Table 1](#). The main analytical technique for determining breath (and blood) alcohol concentrations for over 100 years has been the oxidation of alcohol by potassium dichromate and sulfuric acid (acid dichromate) as follows:

This reaction could be measured by titration, or as in the case of breath alcohol testing, by measuring the color change, a decrease in the yellow color of potassium dichromate. As this method uses toxic chemicals and is slow and cumbersome and difficult to automate, it has been replaced by other analytical methods.

Table 1 Major historical developments in breath alcohol testing

Year	Development
1803	Henry's law that a fixed ratio occurs between a volatile in a liquid and air at equilibrium at a constant temperature was published. It is the basis of breath alcohol testing
1835	The oxidation of alcohol by acid dichromate is described by J. Liebig
1867	Breath alcohol concentrations were determined by F.E. Anstie using an acid dichromate solution. He first reported the mouth alcohol effect
1910	The applicability of Henry's law to the distribution of volatile substances between blood and alveolar breath was reported by A.R. Cushny
1927	E. Bogen first described the use of breath alcohol testing for medicolegal purposes and proposed a blood to breath alcohol ratio of approximately 2000:1
1931	R.N. Harger of Indiana University developed the first portable breath alcohol testing instrument to be used by the police
1954	R.F. Borkenstein of Indiana University developed the Breathalyzer [®] , which measured BrAC by a potassium dichromate/sulfuric acid method. It was the most successful and the most widely used breath alcohol testing instrument for law enforcement purposes. Approximately, 30 000 Breathalyzers [®] were manufactured worldwide until production ceased in 1997
1964	The Grand Rapids Study (a roadside survey), published by R.F. Borkenstein, determined by breath alcohol testing the increased risk of causing a motor vehicle collision with increasing BAC. A legal limit of 0.08 g/100 ml (17 mmol l ⁻¹) was proposed. This study had a major impact on drinking and driving laws in North American, Europe, and Australia
1970	A small gas chromatograph for breath alcohol testing was developed by J.R. Penton and M.R. Forrester
1971	R.A. Harte described a portable IR breath alcohol testing instrument called the Intoxilyzer [®]
1972	Fuel cell (electrochemical) based breath alcohol testing was described by H.W. Bay, K.F. Blurton, H.C. Lieb, and H.G. Oswin
2001	A portable mass spectrometer to determine breath alcohol concentrations was developed by P.F. Wilson et al.

Alcohol in the Blood and Breath

Once an alcoholic beverage is consumed orally, the alcohol diffuses quickly from the stomach and small intestine into the blood. The blood is pumped by the heart throughout the body, and the alcohol is distributed to the various tissues according to their water content. The blood, which contains alcohol, is pumped by the right side of the heart via the pulmonary artery to the lungs. The lungs have approximately 250 million small pear-shaped sacs known as alveoli. As there is approximately 100 ml of blood in the lung capillaries, at any given time, in effect, a thin film of blood is spread over the large surface area of the lungs, which facilitates the rapid diffusion of volatile compounds (such as oxygen, carbon dioxide, and alcohol) from the blood into the breath. The diffusion of alcohol from the blood into the breath is based on Henry's law.

When the BAC is increasing, the arterial BAC is greater than the venous BAC. As breath alcohol concentrations (BrACs) are based on the arterial BAC in the lungs, and venous blood samples are generally collected from the cubital vein in the

arm, the BrAC can be greater than the venous BAC during this period of time. However, the brain alcohol concentration (and hence alcohol-induced impairment) is related to the arterial BAC. BrACs, therefore, provide a more accurate indication of impairment than the venous BAC, when the BAC is increasing.

During exhalation, the temperature of the breath decreases from body temperature (~37 °C) to breath temperature of approximately 34 °C. This occurs as the breath returns heat and moisture to the mucous lining of the upper respiratory tract (URT) in order to minimize water and heat loss during breathing. The interaction of alcohol in the breath with the URT causes the blood to breath alcohol ratio (BBR) to be approximately 2300–2400:1 during a forced exhalation.

There are three main phases of the BrAC curve during a forced exhalation. The first part of breath exhaled is the tidal phase, where the breath from the URT (dead space), which contains little alcohol, is exhaled. The BrAC then increases rapidly as the breath containing alcohol from the lungs is reached. Finally, an approximately level profile, or plateau, of the BrAC is obtained during the final stage of exhalation.

Hyperventilation can cause the BrAC to be lowered by approximately 10%, and likewise, hypoventilation can cause the BrAC to be increased by 10%. However, the effect of these breathing techniques on BrAC disappears virtually as soon the person resumes normal breathing.

Body temperature may also affect the BrAC. *In vitro* testing using alcohol simulators has shown that a 1 °C increase in the temperature of the solution caused an approximately 6.5% increase in the vapor alcohol concentration. *In vivo* testing with drinking human subjects has shown that the change in BrAC is much less affected by body temperature.

Analytical Methods

Most of the breath alcohol testing instruments currently used for law enforcement purposes employ one of the following techniques.

Infrared Spectrophotometry

This is the most common analytical technique for evidential breath alcohol testers used by the police. The breath alcohol (CH₃CH₂OH) concentration is determined by the absorption of infrared (IR) light according to the Lambert–Beer law as follows:

$$I = I_0 e^{-abc}$$

where *I* is the final intensity of IR light (e.g., when end-expired breath sample is in the sample chamber); *I*₀, the initial intensity of IR light; *e*, the mathematical constant (2.71); *a*, the absorption coefficient of alcohol; *b*, the path length (the distance IR light travels through the sample chamber); and *c*, the concentration of alcohol vapor in the sample chamber.

In the 1970s when IR breath alcohol technology was first developed, the path length (*b*) of breath alcohol instruments was required to be several meters long in order to obtain the maximum change in intensity of IR light (*I*) for detection. With improvements in IR technology, the necessary path length has

been reduced to centimeters and thus has reduced the size of these instruments.

Different IR wavelengths have been employed to increase the specificity of IR breath alcohol testing, such as:

3.39 μm : asymmetrical stretching vibration of the methyl group ($-\text{CH}_3$)

3.48 μm : symmetrical stretching vibration of the methyl group

9.4 μm : stretching vibration of the C–O bond

Other wavelengths have been employed to measure carbon dioxide and water vapor concentrations in the expired breath to assist in the determination of a uniform breath sample and potential mouth alcohol effects (MAEs).

2.77 and 4.26 μm : carbon dioxide

2.57 μm : water

Electrochemical (Fuel Cell)

The concentration of the alcohol in the end-expired breath sample is oxidized by an immobilized electrolyte, a working electrode, and a counter electrode to produce an electrical current. The electrochemical reactions are as follows:

at the working electrode, and;

at the counter electrode.

The disadvantage of electrochemical analysis of breath alcohol compared to IR is that only the end-expiratory BrAC is determined (one data point), whereas IR measures the entire exhalation BrAC curve.

Dual IR/Electrochemical

IR and electrochemical techniques have been combined in some breath alcohol testing instruments. Typically, IR monitors the BrAC curve during exhalation and the end-expiratory BrAC is measured by the electrochemical technique. The two different types of sensors allow for greater specificity.

Gas Chromatography

The end-expiratory breath is passed through a column, which separates the alcohol from the various other components of breath and is then quantified with flame ionization or thermal conductivity detectors. This technique has not gained widespread use as gas chromatographs (GCs) were typically larger and required compressed tanks of nitrogen, hydrogen, or helium. Newer miniature GCs, using scrubbed ambient air instead of pressurized gases in tanks, may increase the use of this technique by law enforcement agencies.

Types of Breath Alcohol Testing Instruments

Passive Alcohol Sensor

The passive alcohol sensor is designed to quickly and easily detect alcohol in the ambient air around the suspected drunk

driver. It is the least accurate of types of breath alcohol testing instruments as end-expiratory breath is not tested directly and may be affected by ambient conditions around the tested driver.

Screening Device

As it is difficult for the police to detect alcohol impairment in alcohol-tolerant, heavy drinkers by physical observation alone, a handheld device, typically using an electrochemical sensor, which samples the end-expired breath of the suspected drunk driver, provides the police with grounds to demand an evidential breath alcohol test.

Alcohol Ignition Interlock Device

These devices are usually installed in an automobile as a result of a court order or conditional licensure for convicted drinking drivers. The driver is required to provide an end-expired breath sample into the alcohol ignition interlock device (AIID) before the automobile will start and additionally at random times throughout driving. A FAIL recorded by the AIID (typically at BACs of 0.02–0.04 g/100 ml (4–9 mmol l⁻¹)) will result in the automobile not starting, the lights flashing, or the horn honking loudly. AIIDs when installed have been found to reduce the incidence of alcohol-related motor vehicle collisions.

Evidential Breath Alcohol Instruments

These instruments are the most reliable, sophisticated, and accurate of all types of breath alcohol testing instruments. Evidential breath alcohol testing instruments usually are based on multiple IR wavelengths or dual IR/electrochemical testing. A typical evidential breath alcohol testing sequence is shown in Table 2.

A 15–20 min pretest observation/deprivation period will prevent the MAE. Air blanks are conducted throughout the testing sequence to ensure that the ambient air is free of alcohol or other potential interfering volatile substances and that the evidential breath alcohol testing instrument has been cleared of any alcohol vapor from previous testing. A calibration check (involving a wet-bath simulator or pressurized dry gas) of a known alcohol vapor concentration ensures that the instrument is measuring alcohol vapor accurately. Two breath tests with good duplication (usually within 0.02 g/100 ml (4 mmol l⁻¹)) increases the reliability of breath alcohol testing of the drunk driver. The computerized, automatic breath alcohol testing sequence and printing of the results

Table 2 An example of an evidential breath alcohol testing sequence

Fifteen to twenty minute observation/deprivation period

eliminates the possibility of any real or alleged manipulation of the evidential breath alcohol testing instrument by the police operator.

Forensic Issues

As several million evidential breath alcohol tests are conducted on suspected drinking drivers throughout the world every year, it is not surprising that many forensic issues have been raised in criminal court. The main three issues are as follows.

Blood to Breath Alcohol Ratio

Breath alcohol testing instruments in many countries are calibrated on the BBR of 2100:1. That is, 2100 ml (2.1 l) of end-expired breath is deemed to have the same amount of alcohol as 1 ml of blood. The BBR in drunk drivers has been found to be closer to 2300–2400:1. BBRs > 2100:1 in a person will mean that the BAC is underestimated, and BBRs < 2100 will mean the BAC is overestimated. Therefore, using breath alcohol instruments calibrated at 2100:1 will underestimate the BAC of drunk drivers by 10% or more on average.

A wide range of unrealistic BBRs have been used in criminal court to dispute the validity of breath alcohol testing. Most of the ranges have been due to the low BAC at which the BBR was determined. As with all ratios, the BBR has greater variability at lower BACs, as shown in Table 3.

A ± 0.005 g/100 ml (1 mmol l^{-1}) variation in BrAC at a BAC of 0.012 g per 100 ml (3 mmol l^{-1}) can produce an apparently enormous BBR range of 1482–3600:1. The BBRs determined at these low BACs have been applied incorrectly at the typically high BACs (on average 0.150 g/100 ml (33 mmol l^{-1}) in most countries) found in drunk drivers.

Field studies of evidential breath and blood alcohol testing in several countries have shown that instruments calibrated at a BBR of 2100:1 will only rarely (<1%) overestimate the actual BAC, and in those cases, the overestimate is usually <0.01 g per 100 ml (2 mmol l^{-1}). However, in order to avoid much needless legal arguments, most countries have now changed their drunk driving laws to include not only a per se BAC limit but also a BrAC. In the United States, the common BrAC limit is expressed in g/210 l of breath, which basically enshrines a BBR of 2100:1 by law.

Mouth Alcohol Effect

The BrAC can be falsely elevated if there is residual alcohol from a last alcoholic drink or an alcohol-containing fluid (such as mouthwash) remaining in the oral cavity at the time of the

breath test. The MAE, however, disappears rapidly in an exponential decrease and will only cause false elevations in BrAC for 15–20 min at most. The MAE is less when the alcohol concentration of the beverage is low (such a beer at 5% v/v alcohol rather than liquor (40% v/v alcohol), when the beverage is swallowed rather than gargled, when the subject opens his mouth and talks and when salivation is stimulated (such as when chewing gum). Dentures, chewing tobacco, or gum in the mouth do not significantly prolong the MAE.

As alcohol rapidly leaves the stomach and stomach concentrations are typically <1% alcohol v/v shortly after drinking has ceased, belching, burping or gastroesophageal reflux disease, or a hiatus hernia will not produce a significant, long-lasting MAE.

In addition, evidential breath testing procedures that include a 15–20 min deprivation or observation period before testing and two breath samples with good agreement will preclude a significant MAE occurring during routine evidential breath alcohol testing of drunk drivers by the police. Some evidential breath alcohol testing instruments (usually, IR) also have a mouth alcohol detection system as an additional safeguard against the MAE.

Specificity

In order for a nonalcohol compound to produce a false-positive breath alcohol test result, it must be a volatile organic compound that is relatively nontoxic. The main endogenous compound that could produce a false-positive BrAC is acetone. Acetone can be found in relatively high concentrations in the breath of uncontrolled diabetics, fasting individuals, and people on a high-protein low-carbohydrate diet. All current evidential breath alcohol testers, however, are not affected by acetone.

Exogenous compounds that could potentially cause a false-positive BrAC include mainly glues, paints, and solvents. These volatile compounds are eliminated from the breath exponentially in a similar manner as for the MAE, upon exposure to fresh air. Solvents also tend to have significant toxicity and have characteristic odors. As a result, solvent inhalation would not be expected to remain undetected during routine evidential breath alcohol testing.

Conclusion

Breath alcohol testing has been of critical importance in the enforcement of laws against drunken driving in many countries and has greatly enhanced traffic safety by decreasing the incidence of drinking and driving. Several million

Table 3 Apparent blood to breath alcohol ratios (BBR) when breath alcohol concentration is within ± 0.005 g/100 ml (1 mmol l^{-1}) of the blood alcohol concentration

BAC (g/100 ml)	BrAC range (± 0.005 of BAC)	Apparent BBRs
0.012 (3 mmol l^{-1})	0.007–0.017 ($2\text{--}4 \text{ mmol l}^{-1}$)	1482–3600:1
0.040 (9 mmol l^{-1})	0.035–0.045 ($8\text{--}10 \text{ mmol l}^{-1}$)	1867–2400:1
0.080 (17 mmol l^{-1})	0.075–0.085 ($16\text{--}19 \text{ mmol l}^{-1}$)	1976–2240:1
0.150 (33 mmol l^{-1})	0.145–0.155 ($32\text{--}34 \text{ mmol l}^{-1}$)	2032–2172:1

evidential breath alcohol tests are conducted globally each year and have gained widespread public support. Such issues as the BBR, MAE, and specificity have little scientific merit in routine evidential breath alcohol testing involving proper scientific controls such as duplicate breath tests, a preliminary deprivation/observation period, and calibration checks as part of the breath alcohol testing procedure.

Introduction

The consumption of alcohol by the community in many parts of the world continues at a significant rate. For example, per capita consumption in most of Europe as well as United States, Australia, and New Zealand ranges from 8 to 12 l. The main types of alcoholic beverages are beer, wine, and spirits, although each category comprises many different products, made from different ingredients and by different processes. Moreover, the concentration of alcohol varies between these products, from about 2–6% for beer, about 10–12% for wine, and over 20% for spirits and liqueurs.

While alcohol (chemically, ethanol) is the main active substance, several other constituents are also present that contribute to the taste of these beverages. Many of these constituents are volatile and can be analyzed to determine the source and type of alcoholic beverage.

The lower-molecular-weight alcohols have been used to characterize the source of particular types of alcoholic beverages, that is, beer, wines, and spirits. These substances are often termed congeners. While these are not individually characteristic of a particular alcoholic beverage, their combination can sometimes be used to help determine the source and type of alcoholic beverage.

Congener Content of Beverages

In beer, a number of volatile compounds contribute to the odor and flavor. These include acetaldehyde, ethyl acetate, 1-propanol, 2-methyl-1-propanol, 2-methyl-1-butanol, 3-methyl-1-butanol, isoamyl acetate, 2-phenyl-ethanol, 2-phenyl-ethyl acetate, and many others. In wines, there are hundreds of substances that contribute to the color and taste including lower and high alcohols, phenols, esters, and terpenes.

Congeners of the type listed above and in Table 1 are present in quite low concentrations, but most of them are detectable using modern analytical techniques. Their source depends on the type of fermentation process, the type of material being fermented, and the remaining processes used to prepare the final product.

Methanol derives from bacterial action on pectin, a heteropolysaccharide commonly found in fruits and, as such, it is found in the highest quantities in brandies made from apples, plums, and cherries.

The higher alcohols are byproducts of fermentation and depend on the source of the sugars used in the fermentation and the presence of amino acids.

The quality and type of the distillation process will also affect the content of the congeners. Vodka contains some methanol but effectively no other congeners, while other alcoholic products contain variable types and content of congeners.

Congener analysis has been extensively used to determine the type of whiskey (i.e., Scotch, Irish, and Bourbon), including distinguishing counterfeit whiskeys. The relative amounts of the fusel oils 1-propanol, 2-methyl-1-propanol, 2-methyl-1-butanol, and 3-methyl-1-butanol have been used to distinguish these whiskeys. When the 3-methyl-1-butanol/2-methyl-1-butanol ratio is relatively high (>5.0), a spirit of non-cereal origin is suspected.

In some alcohol products, particular characteristic chemicals can be targeted. For example, (*E*)-1-methoxy-4-(1-propenyl) benzene, or *trans*-anethole is a volatile compound that is found naturally in aniseed (*Pimpinella anisum*), star anise (*Illicium verum*), and fennel (*Foeniculum vulgare*). Extracts of these herbs are used to make ouzo, raki, and the German aniseed liqueur 'Küstennebel.' Consumption of these products does give rise to detectable anethole in serum (maximum blood concentration – $C_{\max}$ 5–18 ng ml⁻¹) at about the same time as alcohol concentrations peak following consumption of low to moderate amounts of the beverage.

Absinthe contains the monoterpenoid ketone thujone and is found in *Artemisia absinthium* and *Artemisia pontica*. Thujone content of all the commercial products are at or below the mandated 35 mg kg⁻¹.

Methods

These volatile congeners including ethanol itself are invariably detected by temperature-programmed headspace-gas chromatography (GC). However, the detection limits are far lower than those used for conventional assays for ethanol. It is uncommon to measure ethanol blood concentrations <0.01 g/100 ml (0.1 g l⁻¹). The blood concentrations of congeners are over 1000 times lower. Consequently, the required minimum detection limits for congeners are at least: 0.5 mg l⁻¹ for methanol, 0.05 mg l⁻¹ for 1-propanol, and 0.02 mg l⁻¹ for the butanols and for methyl ethyl ketone.

^aMean ± SD.

This is achieved by the use of larger volumes of blood (1 ml or more) and the use of salts (i.e., sodium sulfate) to increase headspace concentrations (increases vapor pressure) in the vial. Higher chain alcohols are freed from glucuronic acid by prior digestion with beta-glucuronidase, and to reduce viscosity, water is added to dilute samples. Ultrasonication and/or ultrafiltration can also be used to break up cells. The use of small headspace vials increases sensitivity further.

The net effect of this is to have complex chromatograms. Capillary columns improve the separation of the constituents to the point of using even two columns of different polarity (e.g., CP-Sil-19 and CP-Wax-52); however, the use of capillary columns is difficult when injecting relatively large headspace volumes without high-pressure valves to regulate flow rates.

The best technique is to use cryofocusing in which a short capillary column is inserted before the injector through which refrigerated gaseous nitrogen is passed in the opposite direction to the carrier gas flow. This allows the volatiles to be trapped in the capillary and pressure injected into the analytic columns in a short burst.

While flame ionization detectors can be used to detect the eluting components, the use of mass spectrometry (MS) to identify these components is advisable in modern analytic toxicology. MS avoids the need to use two columns and can with use of retention time allow identification of congeners with much more certainty.

It is recommended to store blood samples in a frozen state at –20 °C until analysis to avoid loss of congeners and to reduce other changes that might occur, that is, putrefaction, although in sealed tubes, the stability of ethanol and congeners is quite good for at least a few months when stored at 4 °C. Putrefactive changes will lead not only to a discoloration of the blood but also to the formation of 1-propanol, 1-butanol,

acetaldehyde, and other substances that elute in the chromatogram.

For the analysis of actual alcoholic beverages, similar GC methods can be employed using the headspace; however, more sophisticated methods have been employed using solid-phase microextraction fibers and GC–MS including two-dimensional GC with time-of-flight MS (GC–TOF–MS).

Disposition

All congeners appear to be well absorbed when consumed in alcoholic beverages; however, their distribution in the body increases as their solubility in fatty tissues increases. For example, ethanol is distributed to the water content of the body whereas the higher chain alcohols are distributed into the non-water compartments of cells and consequently have a higher volume of distribution, often as much as double that of ethanol.

The higher chain alcohols are also conjugated with glucuronic acid. For example, 1-propanol is conjugated to about 30%, 1-butanol is conjugated to about 40% and 2- and 3-methylbutan-1-ol are almost completely conjugated. There is some conjugation of ethanol; indeed, ethyl glucuronide can be used as a marker of alcohol exposure as it has a longer elimination half-life than ethanol itself, and its presence in blood and hair is used to assess the degree of chronic alcohol exposure. In some European countries, it is used to assess abstinence to ethanol and to provide an objective measure to regrant a driving license following loss of license for alcohol-related driving offenses.

The elimination of these congeners is complex. All alcohols are substrates for alcohol dehydrogenase (ADH); hence, the

overall oxidation of the alcohols will depend on the overall quantity and type of the alcohols. As the ethanol concentration will usually be much greater, the amount of ethanol will affect the rate of metabolism of other substances by this route (Table 2).

There are differences in the concentration of congeners between blood and serum (plasma); hence, it is necessary to standardize on the specimen being analyzed.

Methanol

Methanol is an endogenous compound found in humans not consuming alcoholic beverages, particularly in persons consuming fruit, but it does not appear to be limited to this food source. Background serum concentrations in unexposed persons are usually well below 3 mg l^{-1} , with an average of around 1 mg l^{-1} or lower.

Consumption of methanol-free ethanol can cause significant rise in serum methanol concentrations at a rate of $0.1\text{--}0.5 \text{ mg l}^{-1}$ per hour. The net increase depends on the length of exposure to ethanol. This increase occurs because oxidation to formaldehyde by ADH is effectively blocked by the presence of ethanol at concentrations above 0.2 g l^{-1} . However, methanol is also removed by other processes, particularly through breath, hence its pharmacokinetics, as with all congeners, is complex.

Most alcoholic beverages contain small amounts of methanol, which further increase the serum methanol concentrations. In chronic alcoholics, methanol concentrations can easily exceed 10 mg l^{-1} . The presence of significant amounts of methanol in blood (10 mg l^{-1} or greater) can be used as a guide to suggest chronic alcohol abuse; however, the drinking pattern and type of alcohol consumed will affect the methanol concentration.

2-Propanol

Background concentrations of 2-propanol (isopropanol) in nondrinkers are usually $<0.1 \text{ mg l}^{-1}$. Acetone, its major metabolite, has much higher endogenous concentrations at about $1\text{--}3 \text{ mg l}^{-1}$. Concentrations in people who drink alcohol rise substantially and exceed 10 mg l^{-1} ; however, mean concentrations are closer to 1 mg l^{-1} . Corresponding acetone concentrations are about fivefold higher. Acetone is also found in persons with diabetic ketoacidosis. There is some evidence of formation of 2-propanol from acetone as well. Some absorption of this alcohol occurs from skin swabs containing this alcohol.

1-Propanol

This alcohol is not present normally in serum but is apparently produced in small amounts when pure ethanol is consumed. This congener is commonly present in alcoholic beverages with contents ranging from near zero for vodka and gin to over 1000 mg l^{-1} in fruit brandies. In beer and wine, the content is about 10 and 30 mg l^{-1} , respectively. Consequently, significant increases in the concentration of this alcohol occur in persons consuming alcoholic beverages containing this congener.

The concentration ratio of 1-propanol with 2-methyl-1-propanol (isobutanol) has been used to determine the source of the alcoholic beverage. Beer drinkers tend to have serum concentration ratios of these two alcohols in the order of 3:1 even though the content of these two alcohols in this type of product is similar, whereas wine drinkers tend to have similar serum concentrations. As 2-butanol concentrations decrease more quickly than 1-propanol, higher concentrations of 1-propanol suggest that some time has elapsed since consumption.

Table 2 Source, metabolic pathway, and some pharmacokinetic parameters of selected congeners

Congener	Source	Metabolism	Volume of distribution (l kg^{-1}) ^a	Elimination half-life (h) ^b
Methanol	Endogenous, all alcoholic beverages	Oxidation to formaldehyde, and formic acid	0.5	1.5–3
1-Propanol	Alcoholic beverages, particularly fruit brandies	Oxidation to propionaldehyde and propionic acid, and propyl glucuronide	0.7	1–2
2-Propanol	Endogenous, alcoholic beverages	Oxidation to acetone, and 2-propyl glucuronide	$\sim 0.7^c$	1–3
2-Methyl-1-propanol (isobutanol)	Alcoholic beverages except vodka; highest in fruit brandies	Aldehyde and acid, and glucuronide	1.3	1–3
1-Butanol	Bacterial formation in putrefaction; fruit brandies	Butyric aldehyde and butyric acid, and glucuronide	$\sim 1^c$	n.a.
2-Butanol	Fruit brandies	Methyl ethyl ketone	$\sim 1^c$	n.a.
2-Methyl-1-butanol	All beverages except vodka	Corresponding glucuronide, aldehyde, carboxylic acid, propionic acid, acetic acid	$>1^c$	n.a.
3-Methyl-1-butanol	All beverages except vodka	Corresponding glucuronide, aldehyde, carboxylic acid, acetoacetic acid, acetic acid	$>1^c$	n.a.

n.a., not available.

^aThese are approximate only and are only meant to reflect overall penetration into tissues.

^bThese half-lives will increase when metabolism is affected by other substances that compete with their breakdown.

^cData unavailable, estimates only.

Isobutanol (2-Methyl-1-Propanol)

This alcohol is not present endogenously and is usually associated with 1-propanol. It is metabolized in the gastric mucosa and much of it is metabolized in the liver during the first pass; therefore, it has a short elimination half-life. Consequently, concentrations of this congener are less than that of 1-propanol even when similar amounts are present in beverages (see also previous paragraph).

2-Butanol

This alcohol is not present endogenously; however, it is present in fruit brandies and is often associated with 1-butanol. 2-Butanol is metabolized in part to methyl ethyl ketone which can also be used to monitor exposure to beverages containing these congeners.

Isomeric Amyl Alcohols

Both 2-methyl-1-butanol (active amyl alcohol) and 3-methyl-1-butanol (isoamyl alcohol) are present almost exclusively in fruit brandies; however, their concentrations in serum are low following consumption of these drinks.

Toxicity of Congeners

As a general rule, while congeners are present in most alcoholic beverages, it is the ethanol that contributes most, if not all, of the toxicity. Ethanol depresses the central nervous system and disrupts many cellular activities including many biochemical pathways. Alcohol-induced acidosis is common and in some situations (e.g., liver disease, poor nutrition) can lead to abnormal glucose metabolism and ketoacidosis. In most cases, toxicity is reversible once ethanol has cleared the body and fluids have been replaced.

Chronic abuse of alcoholic beverages leads to long-term tissue damage particularly erosive gastritis and ulceration of the stomach, liver cirrhosis, peripheral nerve disorders, and various forms of brain dysfunction including loss of memory and dementia, and fetal alcohol syndrome.

Methanol is arguably the most toxic congener primarily through its metabolites formaldehyde and formic acid. However, endogenous concentrations of methanol rarely exceed 1.5 mg l^{-1} , and it is unlikely that the methanol content of the beverages will itself become poisonous unless the beverage is consumed in massive amounts, or the drinker is an alcoholic and the methanol accumulates. Alcoholics are known to accumulate methanol that derives from the beverage consumed and from endogenous formation.

Hip Flask Defense

The hip flask defense relates to the consumption of alcohol after a traffic-related crime before apprehension by police. The detection and quantification of congeners in blood has been used to assist courts in establishing the accuracy of claims made by the defendant in drinking alcohol after driving,

although this has been mainly used in Germany. The detection of congeners is useful only when the type of alcohol consumed after the collision is significantly different from that consumed before, there are no congeners in the alcoholic beverage (other than methanol) consumed post collision, and there has not been more than a few hours' interval. There are various factors that influence the amount of congeners. This applies particularly to understanding the complex pharmacokinetics of the congeners in conjunction with often complex time courses of drinking.

The most useful application of pharmacokinetic calculation is the determination of the likely ethanol content. This requires knowledge or assumed knowledge of the drinking pattern before and after the collision. Unless the drinking pattern before the collision is witnessed and is reasonably reliable, such calculations can be easily criticized. Above all, such calculations require consideration of the likely range of absorption time, elimination rates, and even volume of distribution. For example, the elimination rate of ethanol can vary from $0.01 \text{ g/100 ml per hour (\%/h)}$ to well over $0.025\%/h$. This is dependent on a number of factors, particularly the blood alcohol concentration (BAC) and the regularity of alcohol consumption (induction of enzymes occurs with regular use).

In a 70-kg male person, the consumption of five glasses of red wine over 4 h can lead to BAC estimates of between (approx.) $0.4\text{--}1.0 \text{ g l}^{-1}$ depending on the alcohol content per glass, elimination rate and absorption rate, and extent of ethanol. Consumption of food can significantly lower the BAC. If this person had a motor vehicle collision and left the scene before a BAC could be performed (usually by breath analysis) and consumed further alcohol (four glasses of wine) before being apprehended by the police 2 h later, it will be very difficult to prove he was over the legal limit of 0.5 g l^{-1} at the time of the collision even when the BAC at this point is just over the legal limit. The analysis of congeners is not useful since they will derive from alcohol consumed before and after the collision. However, if vodka was consumed after the collision then the relative absence of congeners (other than methanol) could prove that it was more likely than not that the allegation was true (that is he did drink vodka after the collision).

Due to individual variability, the complex pharmacokinetics, and likely differences in the contents of drinks, congener analysis can be useful only if the amounts of congeners in the possible scenarios are quite different.

Aspiration Inhalation of food and/or gastric contents into the lungs.

Cognition The ability to think and reason.

Gut motility The activity of the gastrointestinal system.

Impairment Decrement in the performance of motor skills and/or cognitive functions.

Michaelis–Menten kinetics Defines the rate of enzymatic reactions by relating reaction rate to substrate concentration.

Neurotransmitter A chemical substance that is used to send signals from a nerve.

Nystagmus Uncontrolled movement of eyes at the extremes of their motion.

Psychomotor skills The ability to coordinate bodily functions such as hand, eye, and feet movements.

Abbreviations

ADH Alcohol dehydrogenase

BAC Blood alcohol concentration (referring to ethanol)

Symbols

$C_{\max}$ Maximum blood concentration

r Widmark factor in l kg^{-1}

w Body weight (usually in kg)

Introduction

Alcohol, or chemically ethanol, is the most common drug used in the community. It is also the most abused and is by far the most common drug associated with forensic matters. Consequently, it is the most common substance analyzed by laboratories engaged in such activities. The interpretation of these results is, therefore, an important task for any laboratory and associated experts engaged by the courts.

The problems related to alcohol abuse range from driving under the influence of alcohol and intoxication leading to violence and criminal activities to intoxication leading to drug-caused death.

An understanding of what alcohol does and how it affects persons with time is vital to the interpretation of cases involving this substance.

Pharmacokinetics of Ethanol

This simple, water-soluble substance is able to permeate to every tissue in the body very quickly. This means that tissue concentrations of alcohol are often similar to blood, particularly if the water component of each tissue is calculated. Hence, if blood is not available, then other fluids and tissues can be used to determine the presence of alcohol, depending on the

circumstances and whether the person is living or deceased. In living persons, breath alcohol is commonly employed to detect the presence of alcohol and, if necessary, to estimate the amount of alcohol in the blood.

It is easily absorbed from the gastrointestinal tract, although it does require 30 min to 2 h for complete absorption. The rate of absorption depends on the gastric emptying time, gut motility, volume of alcohol consumed, and on whether it is consumed with or without food.

Food can reduce the apparent extent of absorption and reduce the maximum blood concentration ($C_{\max}$) achieved after a standard dose. Reductions in this $C_{\max}$ can be as much as 50%. The consumption of large volumes of high-strength alcohol-containing beverages can irritate the gut and reduce the rate of absorption.

Once absorbed, it is rapidly removed through a combination of expiration (through breath) and excretion of unchanged drug in urine but mainly through metabolism as acetaldehyde (most of this is then converted to CO_2) and some ethanol conjugates, such as ethyl glucuronide.

The main metabolic pathway is through alcohol dehydrogenase (ADH) in the liver converting ethanol to acetaldehyde. The rate of metabolism of alcohol by this route is based on Michaelis–Menten kinetics; effectively, however, at concentrations above 0.02% (0.2 g l^{-1} or 200 mg l^{-1}), the rate of removal is near zero-order, which means a constant amount can only be

eliminated, ranging somewhere between 0.01% and 0.025% per hour, and with an average of around 0.015% per hour. If one assumes an elimination rate of 0.015% per hour, then over 3 h, 0.045% alcohol will be removed from the blood, that is, if the blood alcohol concentration (referring to ethanol) (BAC) was 0.10%, then after 3 h, it would be around 0.055%.

When people consume alcoholic drinks over several hours, estimation of the BAC becomes even more complex as elimination is superimposed by the occurrence of multiple absorption peaks, often complicated by the consumption of food during this period. **Figure 1** illustrates what might happen when three drinks are consumed over 3 h.

Persons who regularly consume alcohol will have a higher ADH activity due to induction of enzymes and will often have higher elimination rates, that is, 0.02% per hour or higher.

Regular high-dose consumers can also activate their microsomal enzyme systems to metabolize ethanol, although this is usually relevant only at high BACs, much higher than 0.1%.

Estimation of Dose and BAC

Estimation of the dose can be achieved by using the Widmark equation, following pioneering work by E.M.P. Widmark in the 1930s in which he was able to show the relation between BAC, body weight (w), and dose of alcohol consumed (see below).

$$\text{BAC(g/l)} = \text{Dose(g)} / r \times w(\text{kg})$$

or

$$\text{Dose(g)} = \text{BAC(g l}^{-1}) \times r \times w$$

where r is the Widmark factor in units of l kg^{-1} : for men, this is about 0.68 and for women, about 0.55.

The Widmark factor is actually the volume of distribution for alcohol. This factor is not a constant; rather it shows variation from person to person, as for other drugs.

Figure 1 Alcohol absorption/elimination curve showing top-up peaks. Arrows indicate times at which alcoholic drinks were taken. Reproduced from *Alcohol/body fluids. Encyclopedia of Forensic Sciences*, 2000, Elsevier Ltd.

When the bioavailability of alcohol is not 100%, say after a meal, the dose needs to be corrected for this apparent loss of ethanol. Moreover, corrections are applied to the dose to take into account the elimination of alcohol with time.

For men with a body weight of 70 kg, the dose needed to reach a BAC of 0.5 g l^{-1} (0.05%) is 24 g (almost 2½ standard drinks) if a bioavailability of 100% is assumed. For a woman weighing 50 kg, only 14 g of alcohol (a little less than 1½ standard drinks) is needed to reach this BAC.

Neither estimate has taken into account any elimination of alcohol. Over a period of 2 h, there will be some elimination, but not necessarily the greater part of these 2 h, depending on the rate of absorption.

Effects of Alcohol

Mechanisms and Types

Ethanol has a complex effect on the human body. Primarily, it is considered a depressant of the central nervous system (CNS) as it reduces the ability of the brain and the nervous system to function normally. It does this by a nonspecific depression of nerve and cellular function and by affecting a number of excitatory and inhibitory transmitters such as GABA, dopamine, and serotonin.

The actions on GABA, an inhibitory neurotransmitter, function in a similar manner to that seen with the sedating benzodiazepines and barbiturates. Alcohol also enhances the actions of serotonin (at the 5-HT₃ subtype), a significant receptor system involved in behavior, and the glutamate receptor by inhibiting the opening of voltage-sensitive calcium channels, which are involved in learning and memory.

Two manifestations of alcohol use are disinhibition and increased self-confidence. These often result in gregarious behavior and less restraint over one's actions. Hence, aggression and violence with loud and outrageous behavior are common in 'drunk' persons. Driving skills and related skills requiring good reflexes, and the ability to have good divided attention skills and vigilance is also adversely affected.

Ethanol also increases urine output (diuresis), and dilates blood vessels, which is the reason for the flushed appearance of some alcohol users.

Chronic heavy use of alcohol is associated with diseases of several organs including the brain, liver, and heart, and peripheral neuropathy of the hands and feet. Chronic disease is often associated with general nutritional and vitamin deficiency. In chronic disease, the pharmacokinetics of alcohol is adversely affected, usually leading to a decline in the rate of elimination.

Chronic use of alcohol does lead to tolerance as the body adapts to the continuous presence of ethanol. This has the net effect of reducing the apparent negative effects of alcohol on the brain. Neuroadaptation is a variable process and will differ greatly between persons.

Impairment

The effects on CNS function are probably the most significant from a medicolegal perspective. At BAC in excess of 0.02%, alcohol produces reductions in motor coordination skills such as hand-eye coordination, speech articulation, intellectual

Table 1 Summary of the key adverse effects of alcohol

Reduction in visual acuity and peripheral vision
Reduction in taste and smell
Altered sense of time
Increased reaction time
Reduced hand–eye coordination ^a
Reduced vigilance
Increased body sway and balance ^{a,b}
Presence of nystagmus (horizontal and vertical) ^a
Reduction in cognitive functions (various)
Introduction of disinhibition (talkativeness, gregarious behavior, etc.)

Note: Most of these develop at around 0.02–0.05% and are detectable at a BAC of >0.1%.

^aPart of standard field sobriety tests incorporating the one-leg stand (OLS), walk-and-turn (WAT), and horizontal gaze nystagmus (HZN) tests.

^bRomberg test.

performance, judgement, and sensory discrimination. At this concentration, these deficits are small and are usually not significant. At a BAC of 0.1%, particularly in a person who has not developed significant tolerance, adverse symptoms become quite obvious and include slurred speech, unsteadiness on the feet, and changed behavior (e.g., aggression). In some people, these signs of intoxication occur at lower concentrations, but in tolerant persons, higher concentrations are needed. These are summarized in [Table 1](#).

The sum total of these changes are often termed impairment and are relevant in a forensic context such as the ability to make rational and informed decisions, including the safe driving of a motorized vehicle and consenting to sexual intercourse.

As a general rule, the higher the BAC, the greater the degree of impairment; however, there is a wide individual variation depending on the drinking history and type of incident. At very high BAC (>0.2%), serious toxicity can occur, and by 0.3%, coma is increasingly likely. Depression of respiration is the most serious toxic CNS effect seen at high BAC. Death can occur from respiratory failure at BAC of 0.4%. High alcohol concentrations can also be associated with aspiration of gastric contents.

Activities Associated with Alcohol Abuse

Throughout much of the world, alcohol is the most common substance associated with injury and death, and consequently, it is the most common drug involved in forensic cases. Alcohol in concentrations much above 0.02% causes impairment of cognitive and psychomotor skills, leading to risk taking and an inability to perform and act safely. This is best seen by the substantial involvement of alcohol in motor vehicle collisions in many parts of the world. In such cases, while legal limits for driving are well under 0.10%, the median BAC is often over 0.15%, a concentration at which substantial impairment is present even in persons who have developed some tolerance to alcohol from regular use.

There is also a strong association between violence and abuse of alcohol. Heavy drinking and verbal arguments usually precede violent acts and the victim is as likely as the offender to initiate an altercation, often with BACs well in excess of 0.10%.

Alcohol-Derived Driving Limits

The increasing realization that excessive alcohol consumption was associated with increased incidence of traffic crashes in the early part of the last century led to laws that prohibited the driving of motorized vehicles under the influence of alcohol. This required the assessment of the driver for intoxication, a process that was dependent on the experience and objectivity of the assessor, usually a physician. Professor Widmark of the University of Lund in Sweden developed a protocol for this assessment in the early 1920s to develop a structure for such assessments and reduce variability in outcomes between physicians and also provided significant research into the measurement of this drug and studied its pharmacokinetics.

It was not until much later that an evidence basis was available for such laws and allowed the introduction of legal (blood and breath alcohol) limits. The Evanston study of 1935 from Northwestern University reported that the risk of being involved in a crash increased with BACs, particularly BACs over 0.02%. The Grand Rapids study, published in 1964 by Robert Borkenstein of Indiana University, was the first large-scale epidemiological study in which almost 6000 drivers involved in crashes and many more (almost 8000) not involved in crashes had their breath alcohol measurements taken. It showed that drivers with BACs of 0.05–0.09% were twice as likely to crash as drivers with a 0 BAC. Drivers with BACs of 0.10–0.14% were ten times as likely to have a fatal crash. Since then, these conclusions have been confirmed by several studies showing that at about BACs of 0.05%, the risk of being involved in a crash begins to increase and becomes pronounced when the BAC exceeds 0.10%.

This evidence provided the foundation to develop programs to reduce the prevalence of drunk driving such that alcohol-based road trauma could be reduced, if not eliminated. On the basis of this research, various governments legislated laws that fixed limits to blood (or breath) alcohol concentrations, largely eliminating the need for assessment of impairment in drunk-driving offenses. Some jurisdictions chose 0.05% as the limit at which drunk-driving offenses would start being prosecuted, while others chose 0.08% or 0.02%. Indeed, many countries even have zero limits, although in practice a limit of 0.02% is often applied.

For more serious drunk-driving offenses, such as those where a person is killed, there may still be a need to formally assess the degree of impairment caused by alcohol (or, indeed, other drugs). In the USA, a standardized field sobriety test was established in the 1970s that became known as the drug evaluation and classification program. While this program was designed to detect drug-caused impairment of drivers, it was based on the test for alcohol-caused impairment and included the one-leg stand, the walk and turn, and horizontal gaze nystagmus tests.

Drug Interactions with Alcohol

In forensic matters, when chemical substances have been used, it is common for more than one drug to be involved. While alcohol is the most common, often well over 0.10%, other drugs interact with alcohol and increase the impairment and

other adverse consequences of alcohol use. The most common of these other drugs are the amphetamine-like drugs (dexamphetamine, methylamphetamine, 3,4-methylenedioxymethylamphetamine (or ecstasy), methcathinone, etc.), opiates and opioids (heroin, codeine, methadone, morphine, oxycodone, etc.), cocaine, cannabis (marijuana), synthetic cannabinoids, and legally available sedatives and hypnotics such as the benzodiazepines.

Glossary

Chain-of-custody A concept that ensures forensic evidence is transported and stored securely.

Introduction

In many countries, alcohol is the most common drug encountered in death investigations. However, when alcohol (chemically ethanol) is detected in specimens taken from deceased persons, a number of factors operate, which can affect the concentration of this drug in postmortem cases. This requires a special understanding of the processes that can affect the amount of alcohol in a specimen, and hence the body, in order to streamline analytical tests and their interpretation to provide the best answer possible in the circumstances.

Collection of Specimens

As with any forensic evidence, it is vital that transfer of specimens from one area to another, that is, mortuary to laboratory, or police to laboratory accords with a chain of custody. This means that who had access to the specimen during transportation is known and the sample is properly sealed and is kept under secure storage before and after analysis. The specimen(s) should be kept for a reasonable period after analysis, at least 1 year, to allow legal processes to complete in the event a reanalysis is required. This reanalysis could occur by the original laboratory or another laboratory. When specimens are reanalyzed for alcohol, some months or years later some changes in blood-alcohol concentration (referring to ethanol) (BAC) will be expected because of storage losses. These are discussed in more detail later.

The specimens most likely to be of use to a forensic investigator are blood, vitreous humor, and urine. These are discussed in detail below. Other specimens can be taken, but their interpretation as to the amount of alcohol consumed and the likely effects of alcohol are much less useful than for the other specimens.

Blood

This is the preferred specimen in postmortem situations, as it is for living forensic cases. If the blood specimen has been taken properly and the composition of the blood has not altered, the BAC allows investigators to assess the degree of alcohol exposure and its relevance to the cause of death.

The site of collection of blood will depend on the state of the body, that is, whether there are any traumatic injuries (e.g., following a motor vehicle crash) and the postmortem interval. Blood pooled in the heart is a common specimen and is most

readily taken at autopsy; however, blood taken from a peripheral site is preferred. These sites include the leg or femoral region of the body, the jugular vein, and the upper arm since these are most remote from the torso and are least likely to be affected by artifacts.

The volume of blood needs to be at least several milliliters, sufficient to almost fill a 10-ml collection tube. Ideally, two such specimens should be collected, one can be used for alcohol determination and the other for other drug analyses. If this is not possible then the blood should be divided and a portion is placed into a smaller container and reserved solely for alcohol determination. The collection of blood should be done to minimize contamination by other fluids and when peripheral blood is collected to minimize withdrawing blood from the abdominal region. Some pathologists or forensic technicians tie off the femoral vein to prevent blood coming from the abdominal region. However, this is not always practicable or indeed necessary if the volume withdrawn is kept to a reasonable amount.

Since alcohol can be produced by some bacteria, it is essential that the collection tube containing blood contains fluoride (usually as sodium salt sufficient to produce 1–2% w/v) as preservative. This inhibits bacterial growth. The use of properly sealed containers to reduce evaporative losses of alcohol is also important, particularly, if there is a delay of some days to weeks before analysis occurs. Freezing specimens at -20°C also reduces any artifactual losses or formation of alcohol, if analysis does not occur immediately after the specimen is received.

Vitreous Humor

The liquid in the eye behind the lens is known as vitreous humor and makes an ideal specimen postmortem since it is protected from much of the initial bacterial and other decompositional processes affecting the rest of the body. As a consequence, the alcohol concentration is much more likely to represent the concentration at the time of death, particularly when a significant postmortem interval exists in an otherwise intact body. It can also be obtained without conducting an autopsy and can often be taken in trauma cases where there has been significant blood loss. Consequently, it is recommended to sample and analyze this fluid whenever an alcohol concentration is likely to have some significance. The comparison of the alcohol concentration in this fluid to blood allows an assessment of the likely accuracy of the BAC.

Figure 1 Comparison of blood and vitreous humor alcohol concentrations.

Figure 1 shows the relationship between blood and vitreous humor alcohol concentrations as a scatter plot from paired postmortem cases over a wide concentration range. Vitreous concentrations are on average about 20% higher than blood since the water content is higher than that of blood. It is not recommended to calculate a likely blood concentration for a vitreous concentration since there is not necessarily a constant ratio. This is mainly due to individual differences and the small delays that might occur in the transfer of alcohol from the blood supply to the vitreous humor, particularly during the absorption phase. There is no significant difference in the alcohol concentration between the right and left eyes.

Urine

Urine can be used to supplement blood–alcohol concentration data in the estimation of the amount and timing of ingestion of alcohol. Urine is less subject to fermentation than blood, particularly, in the early stages of decomposition. However, this depends on a number of factors. Persons with urinary tract infections (and have bacteria in their urine) or those with glucose in urine (diabetics) are more likely to produce alcohol in urine postmortem.

Urine can be collected by inserting a needle into the bladder in an intact body (if no autopsy is being conducted), or during the postmortem itself. Urine is also a useful specimen to screen for the presence of other drugs. If the urine is not frozen until analysis, it should contain potassium fluoride preservative (as for blood) to a final concentration of 1–2% w/v.

Although only a very small amount of alcohol is excreted unchanged in urine, the concentrations are generally similar to those in blood. Urine concentrations tend to be slightly lower in the early stages of absorption, since urine in the bladder has a zero or low concentration of alcohol, and tend to be slightly higher during the elimination phase, for the converse reason. The theoretical urine–blood concentration ratio based on their

Figure 2 Time course of blood and urine alcohol concentrations.

respective water content is 1:23; however, in practice it ranges from much less than unity in the first 1–2 h after drinking has commenced to well over unity after this time. Figure 2 illustrates the time course of concentrations in blood and urine in volunteers given a standard dose of alcohol.

Given these variable ratios depending on the timing of alcohol ingestion and individual differences in alcohol pharmacokinetics, it is not advised to actually use urine alcohol concentrations to estimate BAC.

Kidney function as assessed by creatinine can sometimes improve estimates of drug excretion, but this does not appear to offer any advantages over uncorrected urine volumes.

Analysis

The same methods used in living subjects are applicable to postmortem specimens. In particular, the use of GC-based methods is much preferred over nonchromatographic methods since they are more specific and can easily differentiate other low-molecular-weight compounds that may be present in the specimen. These compounds include acetone and isopropanol that can be present in persons with diabetic ketoacidosis, as well as methanol and other low-molecular-weight alcohols (congeners). In forensic cases, it is mandatory to use GC methods, either by liquid injection or by headspace analyses.

Postmortem Changes in Blood Concentration

There are a number of processes that have the ability to affect postmortem alcohol concentrations. These are summarized in Table 1 and show that both increases and decreases can occur in the blood concentration of alcohol after death. This increases the complexity of interpretation and makes it even more necessary for toxicologists and other persons to consider all relevant factors before making a judgment on the significance of the result.

In cases of gross decomposition, it is unlikely that any measurement for alcohol (and indeed other drugs) will lead to any real resemblance to the concentration at the time of

Table 1 Types of processes affecting postmortem alcohol concentrations*Type of process*

death or provides practitioners an ability to estimate the actual concentration. This may also be the case for severely traumatized bodies, depending on the site(s) of trauma relative to the site of blood collection. Bodies submerged in water for extended periods are not only liable to be grossly decomposed but also the water itself may affect the concentration of alcohol.

Putrefactive Formation

Putrefactive formation of alcohol occurs when certain bacteria are present in the body either before sample collection or after sample collection and a substrate exists for the formation of alcohol (a sugar) in much the same way as fermentation proceeds for exposed food (e.g., fruit). This process is variable but is much more likely when bodies have been exposed for a day or more at warmer temperatures. BACs exceeding 0.1% are very likely in putrefied bodies. Putrefactive alcohol can be distinguished from consumed amounts by the measurement of vitreous humor, and/or urine, if vitreous is not available. Much lower, or even near-zero, concentrations in these specimens when blood is positive indicate postmortem formation of alcohol.

The measurement of the metabolite ethyl glucuronide in blood or urine also helps to identify the source of alcohol since this is formed by metabolism in a living body. It has been shown that certain bacteria are capable of forming ethyl glucuronide in urine when alcohol is present, hence its presence may not necessarily confirm that the person has consumed alcohol before the death.

When part putrefactive alcohol and consumed alcohol is present, it is very difficult to estimate with any accuracy the likely BAC at death.

Inhomogeneity of Blood

When a person dies, the blood settles in the body according to gravity. This inevitably leads to blood that no longer is as homogenous as during life resulting in a higher or lower hematocrit depending on where the blood was taken and the position(s) of the body. Other bodily fluids may also mix resulting in small variations in the alcohol content depending on the water content of the collected specimen. Taking more than one blood specimen from different parts of the body can help to average out these changes if accuracy is required for the BAC, although this is rarely necessary.

Diffusion and Redistribution

Diffusion of unabsorbed alcohol from the stomach and intestines will occur after death, hence any blood collected near these regions are likely to incur postmortem increases in alcohol content. Artifactual increases can also occur in bodies that have aspirated and alcohol can be absorbed in the lungs themselves. Quite large local increases in alcohol content can occur in certain circumstances. The collection of blood at a peripheral site, such as the leg or arm regions, is recommended to reduce this phenomenon. Again comparing blood concentrations with that obtained in vitreous humor and/or urine is useful to see if this phenomenon might be operating.

Embalming

On occasions, bodies are prepared for a burial before death is investigated by the local authority responsible for the death investigations, that is, coroner, medical examiner, or police. Sometimes, these bodies are embalmed to better present the body to the funeral process. The process of embalming involves the infusion of special fluid into the body, which acts to slow down the decomposition process. This fluid contains various chemicals and often contains ethanol. Consequently, the infusion of ethanol-containing fluids will artificially raise any BAC that might have existed before the embalming process. When this occurs, it is not possible to rely on any measurements in specimens taken from the body.

Stability of Alcohol

It is likely that the concentration of alcohol will slowly decrease with time because of a combination of evaporation, chemical breakdown, and/or enzymatic breakdown, particularly, by bacterial enzymes. A number of bacteria are capable of consuming alcohol, indeed as there are bacteria that can even form alcohol. These losses can occur both in the body and after collection. Storing bodies refrigerated before collection reduces this phenomenon as it does for other postmortem changes; however, there is no control over the postmortem period outside the mortuary. Storing blood in tubes containing fluoride and keeping refrigerated (or even frozen) also minimizes this process.

Losses of alcohol in sealed tubes stored at 4 °C over 1 month are minimal but can amount to about 0.02% over 12 months depending on the sample. This loss could be expected to occur within about 6 months if the blood is stored at room temperature.

Reporting Alcohol Concentrations

The units used to report alcohol concentration varies from one laboratory to another. For example, in Australia, alcohol is most commonly reported as gram percent (g%) or gram per 100 ml but can be reported as milligrams per 100 grams, milligrams per 100 ml, and even as millimole per liter. In many cases, the reporting units are based on legislative requirements. Examples of the different reporting units and how they compare is illustrated in [Table 2](#).

Table 2 Concentration units used to report blood–alcohol concentration in clinical and forensic science

mg ml^{-1} or g l^{-1}	mg 100 ml^{-1} or mg dl^{-1}	g 100 ml^{-1} or $\text{g\%, w/v}$	g kg^{-1} or $\text{mg g}^{-1\text{a}}$	mM or $\text{mmol l}^{-1\text{b}}$
0.50	50	0.05	0.47	10.8
0.80	80	0.08	0.76	19.1
1.00	100	0.10	0.95	21.7
2.00	200	0.20	1.89	43.4
5.00	500	0.50	4.74	108.6

^aThe unit used in Scandinavia and Germany assuming a specific weight of 1.055 for the whole blood, that is, 1 ml = 1.055 g.

^bThe SI unit used in clinical chemistry ($\text{mg ml}^{-1} \times 1000/46.05$), where 46.05 is the molecular weight of ethanol.

The quantification of alcohol needs to proceed with sufficient accuracy and precision to ensure reliability in the interpretation of the results; however, it is not necessary to report with the same level of precision that accompanies a forensic matter in a living person, such as a BAC in a drink-driving matter. This is because, as we have seen, there are a number of factors that affect the concentration in a postmortem setting. This means that reporting to two significant figures is usually sufficient. For example, when reporting as gram per 100 ml of blood, a concentration of 0.142 g% should be reported as 0.14 gram per 100 ml (g%). If 0.142% is reported, the result implies accuracy to this third decimal place that in reality is not possible even with the most precise methods. In reality, a number of processes may have affected the concentration both up and down, and so it is not necessary to have the same reporting accuracy as is required for living cases.

Examples

1. A partly decomposed body was found in the wreck of a motor vehicle that had run off the road and ran into a large tree. The crash was possibly a few days before with weather conditions very warm. Blood from the heart and vitreous humor had alcohol concentrations of 0.08 and 0.01%, respectively. Urine was not available for collection. The large differences in the readings with vitreous showing little if any alcohol suggest the driver did not have significant alcohol present at the time of his death.
2. A body was found deceased on the floor of her home. She had a history of heart disease and may have died one or more days before. A number of whiskey bottles were scattered around the house. Blood taken from the femoral vein, urine, and vitreous humor gave alcohol concentrations of 0.19, 0.22, and 0.21%, respectively. The similarity of these readings with slightly higher concentrations in urine and

vitreous humor strongly suggests that the BAC represented the content at her death.

EtS Ethyl sulfate
FAEE Fatty acid ethyl ester
PEth Phosphatidylethanol

Introduction

The main biotransformation product of ethanol (EtOH) is acetic acid, which is produced by the oxidative pathway catalyzed by alcohol dehydrogenase. Although it accounts for more than 95% of the dose, it is not useful for diagnostic purposes and will therefore not be considered in this article. With less than 5% of EtOH being excreted into urine unchanged, the metabolites described here collectively account for less than 1% of the dose. Nevertheless, they are very useful diagnostic markers for EtOH consumption.

EtOH undergoes metabolism by phase II processes. A small fraction of EtOH is conjugated by uridine diphosphate-glucuronyltransferase to ethyl glucuronide (EtG) or with activated sulfate to ethyl sulfate (EtS). Another phase II reaction was described in 1972 with the formation of ethyl phosphate (EtP) in the liver of rats pretreated with large doses of EtOH.

Formation of fatty acid ethyl esters (FAEEs) is another described nonoxidative EtOH metabolic pathway, mainly formed via the enzyme *O*-acyltransferase. Also of interest for the detection of alcohol consumption is the EtOH metabolite phosphatidylethanol (PEth), which was detected in tissues of EtOH-exposed rats in 1984 and characterized as a specific product mediated by the enzyme phospholipase D. Importantly, PEth is only formed in the presence of EtOH. The chemical structures of metabolites and their formation are depicted in [Figure 1](#).

The detection of the metabolites EtG, EtS, EtP, FAEEs, and PEth can be relevant in forensic toxicology, particularly as the time frame for detection of these metabolites is longer than that of EtOH itself. EtOH may also be detected in decomposed specimens due to fermentation. Therefore, the detection of these direct metabolites of EtOH may assist in differentiating alcohol intake from its presence due to fermentation. Detection of EtG and the FAEEs in hair samples can also be used to determine the history and extent of alcohol consumption.

Because of their implication in forensic interpretation, several methods have been developed to determine EtOH metabolites in conventional matrices such as plasma/blood and urine, as well as in alternative matrices. Indeed, the concentrations obtained in various biological matrices are usually used together to determine the cause of a positive test result.

Ethyl Glucuronide

EtG is a stable, nonvolatile, and water-soluble direct metabolite of EtOH. Although the isolation of EtG in human urine dates back to 1967, its synthesis was not reported until 1995. Since then, it has become commercially available and the added availability of pentadeuterated EtG in 1997 has greatly facilitated investigations into the metabolism and fate of EtOH, and subsequently its detection in a number of biological matrices.

EtG in Urine

After acetylation of evaporated urine and detection by gas chromatography–mass spectrometry, EtG was first quantified in the urine from drunk drivers in 1995. An improvement of the sensitivity and selectivity of EtG determination was the use of silylation instead of acetylation and the implementation of deuterium-labeled EtG (EtG-d₅). The application of the improved method showed a detection time frame up to 75 h in the urine in alcohol-withdrawal patients. Since then, many methods for the determination of EtG have been published. The maximum concentration of EtG in urine has been reported as 1790 mg l⁻¹ in a drunk driver. The implementation of more sensitive instruments such as liquid chromatography–tandem mass spectrometry allows the detection of lower concentrations of EtG in urine by at least tenfold. With the use of these sensitive instruments, very low concentrations of EtG in urine were described after the use of EtOH-containing hand sanitizers, mouthwashes, yeast, and sugar. These findings, in combination with low limits of detection, have led to many debates as to what cutoff should be used to determine intentional EtOH consumption with a current range of 0.1–1.1 mg l⁻¹, with some laboratories recommending even higher cutoffs. A recent development has been the commercial availability of an immunoassay to detect EtG in urine. This now allows laboratories to adopt the convention of screening followed by confirmation of the presence of EtG in urine.

EtG in Blood or Serum

One year after the detection and quantification of EtG in urine, human blood concentrations were first described. Compared to urine, less data are available for blood and plasma concentrations. The maximum concentration of EtG in whole blood

Figure 1 Diagnostically useful metabolites of ethanol.

has been reported as 56 mg l^{-1} , which was found in post-mortem blood. The ratio of EtG in serum/whole blood ranges from about 1.3 to 1.9.

EtG in Hair

The first publication for the determination of EtG in hair appeared in 2000. The advantages of testing for EtG in hair are well documented; hair is relatively noninvasively collected, is difficult to adulterate, and most importantly provides the best retrospective detection compared with other matrices, assuming there is specimen available for collection. Interestingly, the most concentrated hair sample was shown to contain 14 ng mg^{-1} of EtG, which was found in the hair of a socially acceptable alcohol user at autopsy, but the reason for this is unknown.

EtG in Other Specimens

EtG can be detected in various postmortem specimens such as vitreous humor, fat, liver, and bone marrow. Liver showed the highest concentration of EtG with up to $77 \text{ } \mu\text{g g}^{-1}$ tissue. The same study also showed the presence of EtG in bone marrow, which is often still available in cases of extensive decomposition and thus could be a useful tissue where other specimens are unavailable. Vitreous humor has also shown to

be a more reliable matrix than blood, and concentrations of up to 9.4 mg l^{-1} have been detected in this matrix. Vitreous humor is a reliable matrix as it is remote from gut bacteria, which can potentially produce or break down EtG. This phenomenon is complicated by the presence of an already high EtOH concentration in the matrix and/or a urinary tract infection. In addition, the presence of a high concentration of glucose, either due to the consumption of certain foods or the levels produced among diabetics, could potentially result in fermentation followed by the production of EtG from EtOH. The EtG in vitreous humor is far less susceptible to these effects. The average concentrations in cadavers are about 63, 4.3, and 2.1 mg l^{-1} for urine, blood, and vitreous humor, respectively. Thus, although concentrations of EtG in vitreous humor are lower than in either blood or urine, it has been shown to be a more reliable matrix.

Interpretation of EtG Concentrations

The measurement of EtG as a marker for compliance in alcohol abstinence has resulted in many laboratories routinely testing for EtG in urine. Testing for selectivity and robustness are vital when methods are modified by other laboratories to avoid false positive results. The majority of positive samples usually have concentrations below 100 mg l^{-1} . Based on current knowledge, the formation of EtG is not possible without the

presence of EtOH. Interpretation of low EtG concentrations (e.g., below 10 mg l^{-1}) should also factor the possibility of an intake of low amounts of EtOH, for example, in low alcoholic beverages. In cases where trace amounts of EtG (e.g., below 0.5 mg l^{-1}) are detected, the possibility of EtG formation due to the presence of EtOH from other sources (other than alcoholic drinks) should be considered.

Controlled drinking experiments have shown that after the intake of low amounts of EtOH, EtG was detectable in urine. An intake of 0.1 g kg^{-1} body weight (BW) of EtOH showed peak concentrations of $0.2\text{--}8.4 \text{ mg l}^{-1}$ and an intake of 0.5 g kg^{-1} BW showed maximum concentrations of $41\text{--}73 \text{ mg l}^{-1}$. In this study, EtG was detectable in urine for 30 h, whereas EtOH was detectable in urine for only 7 h. Maximum concentrations after an intake of EtOH of 0.2 g kg^{-1} BW is about $0.7\text{--}2.9 \text{ mg l}^{-1}$. Due to interindividual differences in absolute EtG urine concentrations and the influence of several factors (e.g., dilution of urine), it is not possible to estimate the amount of EtOH consumed based on EtG concentrations in urine.

Blood EtG concentrations are significantly lower than those in urine with the majority of published levels below 10 mg l^{-1} . These studies show no correlation between blood EtOH and blood EtG concentrations. Consequently, back calculations of the amount of EtOH consumed prior to sample collection are not possible if only EtG is present in the blood. Low blood concentrations of EtG can result from heavy drinking many hours prior to sample collection or resulting from the intake of small amounts of alcohol shortly prior to collection. Maximum EtG blood concentrations are about $0.3\text{--}0.5 \text{ mg l}^{-1}$ after intake of 0.5 g kg^{-1} BW of EtOH. Maximum concentrations of EtOH are reached between 0.5 and 2 h after controlled intake of EtOH, whereas maximum EtG concentrations are reached between 3.5 and 5 h. The EtOH/EtG ratio in blood (EtOH in g l^{-1} vs. EtG in mg l^{-1}) is >1 in the first 2.5 h after ingestion, after which it drops to <1 until EtG is no longer detectable. Therefore, a ratio of EtOH/EtG <1 may indicate that the alcohol had been ingested more than 2.5 h before sampling. Although a single intake of alcohol is relatively uncommon in communities where drinking is acceptable, this ratio could help to interpret alleged drinking after driving. For the interpretation of EtG concentrations in blood after multiple ingestions of alcohol, interpretation is not as straight forward and no simple rules are currently available.

For the interpretation of a person's history of alcohol abuse, hair analysis for EtG can be useful. However, false negative results also occur. In hair samples from social drinkers, the detection of EtG is uncommon. In 2005, EtG hair concentrations below 8 pg mg^{-1} appeared to be suggestive of teetotalers and those containing above 25 pg mg^{-1} suggested chronic alcohol abuse. However, concentrations above 25 pg mg^{-1} of EtG in hair have been detected in social drinkers and, conversely, concentrations below 25 pg mg^{-1} have been detected in hair samples from known alcoholics, suggesting that the use of such cutoffs in hair may not be appropriate to distinguish these groups.

In postmortem samples, the detection of EtG is a marker of antemortem alcohol consumption and can distinguish from postmortem formation of alcohol from microbial contamination or fermentation in the body after death. However, it has also been shown that EtG can be degraded by bacteria present during decomposition processes where fresh clinical urine

specimens with confirmed bacterial growth showed a degradation of spiked EtG of 60–100% after 5 days of storage at room temperature. Other markers like EtS or EtP may be useful for the determination of antemortem consumption. Based on current knowledge, the presence of EtG in postmortem samples indicates alcohol consumption antemortem in most cases. However, the absence of EtG does not exclude the possibility of alcohol consumption antemortem due to possible degradation.

Ethyl Sulfate

EtOH undergoes conjugation with sulfates via the enzyme sulfatransferase. In 2004, EtS was found to be present in humans after ingestion of EtOH. Since the first reporting of EtS as a human metabolite, there are few data to suggest its presence in human urine from subjects either withdrawing from alcohol abuse or in postmortem tissues. In urine, the maximum concentration that has been found is 264 mg l^{-1} . As for EtG, the concentrations of EtS detected in urine also vary considerably, although there appears to be a weak correlation between EtG and EtS concentrations in postmortem urine samples.

In general, EtS is often not detected in blood samples from either social drinkers or alcoholics. Nevertheless, persons who had considerable exposure to EtOH had average concentrations of 55, 1.8, and 0.9 mg l^{-1} for urine, blood, and vitreous humor, respectively. Up to 4.1 mg l^{-1} of EtS can be detected in vitreous humor. Currently, no method for the detection of EtS in hair has been published. EtS may be a better marker for proof of antemortem alcohol consumption instead of EtG due to it being less prone to degradation by bacteria.

Both EtG and EtS have been found in wine with concentrations of EtS up to ten times higher than concentrations of EtG.

Ethyl Phosphate

EtP was first described in animal studies in 1972. The study reported the presence of EtP in the liver of rats pretreated with high doses of EtOH. The concentrations of EtP found in the postmortem urine specimens are substantially lower than EtG and EtS concentrations. A maximum concentration of 0.15 mg l^{-1} occurs 2 h after the ingestion of a single dose (0.2 g kg^{-1}) of EtOH. There are few other data on EtP concentrations and its potential use as a marker to detect alcohol consumption.

Fatty Acid Ethyl Esters

In the past, the detection of FAEs was mainly used to explain organ damage caused by heavy EtOH consumption. In 1989, Laposata et al. demonstrated the use of FAEs in adipose tissue as a possible marker for chronic EtOH ingestion. In the last years, these metabolites have been detected in various specimens for forensic medical purposes. Whole reviews are dedicated exclusively to the subject in different matrices, such as meconium and hair, and the interested reader is referred to these for more information.

FAEEs in Hair

In forensic toxicology, FAEEs are mainly detected and quantified in hair. More than 15 FAEEs have so far been detected, but only four esters – ethyl myristate, ethyl palmitate, ethyl oleate, and ethyl stearate – have been chosen as markers of EtOH consumption, as they have the highest concentrations in hair. The FAEEs are incorporated into hair mainly from sebum due to their high lipophilic properties. The sum concentrations of the four main FAEEs in hair can be up to 44 ng mg⁻¹, a concentration which was determined after autopsy.

FAEEs in Other Specimens

In addition to FAEEs detection in hair, these nonoxidative metabolites of EtOH have also been detected in meconium and various postmortem tissues. Concentrations between 0.065 and 174 ng mg⁻¹ have been observed in the meconium of babies born to women abstaining from EtOH consumption. In the meconium of babies from nonabstaining women, the concentrations ranged from 0.124 to 1268 ng mg⁻¹.

FAEEs have also been determined in postmortem tissues. Due to the lipophilic properties of FAEEs, concentrations in postmortem tissues such as adipose, blood, brain, and liver have been reported. The highest concentrations of FAEEs were found in liver, where values were up to 569 pmol mg⁻¹.

Interpretation of FAEEs Concentrations

FAEEs have been detected in specimens from teetotalers, non-drinkers, and children from women abstaining from alcohol consumption. It is therefore necessary for cutoff levels to be determined to avoid misinterpretation when using FAEEs as a marker for alcohol consumption.

In hair analysis, it is common to use the sum concentration of ethyl myristate, ethyl palmitate, ethyl oleate, and ethyl stearate as a marker of alcohol consumption. For chronic excessive alcohol consumption, a cutoff value of 0.5 ng mg⁻¹ has been proposed.

Meconium analysis faces similar problems as hair in the interpretation of concentrations of FAEEs. Ethyl linoleate appears to be the best marker in meconium analysis for differentiation between abstaining and nonabstaining women due to a sensitivity and specificity of this marker of 88% and 64%, respectively. This low specificity should be carefully considered in the interpretation of meconium analysis as false negative reports can occur.

Phosphatidylethanol

The formation of PEth in rat organs after EtOH treatment was first described in 1984. The formation of PEth in various rat organs occurs via transphosphatidylolation, which is catalyzed by the enzyme phospholipase D. Although PEth was already discussed in 1988 as a possible marker for alcoholism, blood concentrations of PEth were only first described in 1997. Alcoholics have a mean concentration of about 13 μmol l⁻¹ of PEth at the first sampling, and PEth remains detectable for up to 14 days, in contrast with blood EtOH, which could not be detected the morning after admission. PEth concentrations

are the highest in blood of alcoholics compared to other organs and body fluids. This marker can be produced post-mortem in blood if EtOH is present in this matrix. It appears that humans do not have enzymes to break down PEth in blood, and PEth accumulates in the red blood cells, but can be degraded in HepG2 cell lines. PEth is a specific marker of alcohol consumption to humans as it is only detectable after moderate drinking. PEth is not detected in the blood of healthy volunteers following the consumption of a single dose (32–47 g) of EtOH, although it can be detected in people who have ingested much higher doses. In contrast, 75% of students with prolonged alcohol consumption (average 48–102 g day⁻¹ for 3 weeks) have detectable PEth.

PEth concentrations vary substantially between blood and plasma, with only 10–14% of the concentration in plasma as there is in blood. Considering the lipophilic properties of PEth, this marker may not be incorporated in hair in significant amounts.

Therefore, PEth may be considered an appropriate marker for alcohol consumption and abuse, but additional data are necessary to determine its sensitivity and specificity, especially in matrices other than blood.

Summary and Conclusion

Alcohol consumption may be determined not only by the detection of EtOH itself, but also by the measurement of various direct metabolites. The detection of alcohol metabolites is of forensic interest in cases where EtOH is either not detectable or was possibly formed via postmortem decomposition.

The detection of minor metabolites of EtOH in biological matrices provides an ability to obtain more information on the possible consumption of EtOH. Postmortem detection of EtOH is not conclusive of antemortem alcohol consumption due to the possible EtOH formation as a result of microbial contamination or fermentation in the body after death. To avoid misinterpretation, EtG is used as the main direct biochemical marker of antemortem alcohol consumption in a number of biological matrices.

Different markers will have different purposes. For example, the detection of EtG in urine is suitable for the detection of alcohol intake a few days prior to collection, and may be suitable for detecting a single dose. Hair analysis is useful for detecting drinking pattern and possibly monitoring abstinence whereas detection of alcoholism.

Glossary

Clearance A measure of the body's efficiency in eliminating drugs. Clearance is the volume of blood or plasma or mass of an organ effectively cleared of a substance by elimination (metabolism and excretion) divided by time of elimination.

Dose (of a substance) Total amount of a substance administered to, taken up, or absorbed by an organism, organ, or tissue.

Half-life The time required for the amount of a drug or other substance deposited in a living organism to be reduced to one half of its value by normal biological processes, when the rate of removal is approximately exponential.

Pharmacokinetics Process of the uptake of drugs by the body, the biotransformation they undergo, the distribution of the drugs and their metabolites in the tissues, and the elimination of the drugs and their metabolites from the body over a period of time.

Protein binding The process by which a drug binds to proteins in blood plasma. The amount of drug bound to protein determines how effective the drug is in the body. The bound drug is kept in the blood stream while the unbound components are pharmacologically active.

Route of administration Is the path by which a toxic agent gains access to an organism by administration through the gastrointestinal tract (ingestion), lungs (inhalation), skin (topical), or by other routes such as intravenous, subcutaneous, intramuscular, or intraperitoneal routes.

Volume of distribution (V_D) A measure of the apparent space in the body available to contain the drug. Volume of distribution is the apparent (hypothetical) volume of fluid required to contain the total amount of a substance in the body at the same concentration as that present in the plasma, assuming equilibrium has been attained.

Introduction

The analysis of drugs of abuse in forensic toxicology can be performed using any biological specimen. Each one of them has particular characteristics, providing different information with various advantages and disadvantages. Nevertheless, drug analyses are most commonly performed using blood and urine and, more recently, hair.

One of the differences between specimens is the detection window. In blood samples, this time is very short, as most drugs of abuse disappear 8–24 h after consumption; consequently, these specimens can provide some information on

the likely time since the last administration. Urine provides a longer detection time, which ranges from 6 h (for gamma-hydroxy butyrate (GHB) for instance) to 2–3 days, with the exception of chronic users of cannabis in whom this time has been reported to reach up to 30 days. In hair, the detection window is dramatically increased, as drugs can be detected for months or years depending on the length of the lock of hair.

Blood samples are the specimens of choice when impairment of performance and behavior have to be established or when it is necessary to know if a person had been under the influence of drugs.

The aim of this article is to provide an overview of the analysis of drugs of abuse in blood. No reference is made either to the analytical methodologies for these types of cases or to the issues associated with the analysis of postmortem blood, as they are included in other articles. The drugs of abuse covered in this article are the four main classes, amphetamines (APs), cannabis, cocaine (COC), and heroin, with a short reference to other drugs, such as lysergic acid diethylamide (LSD), ketamine, and phencyclidine (PCP). The most abused prescribed drugs, benzodiazepines, are also included.

Types of Blood Specimens

Whole Blood, Serum, and Plasma

Blood is a complex biological fluid consisting of a buffered clear liquid containing proteins, fats, solids, and suspended cells. Blood accounts for 8% of human body weight, with an average density of $\sim 1060 \text{ kg m}^{-3}$. An adult has a blood volume of $\sim 5 \text{ L}$, composed of plasma and several kinds of cells: erythrocytes (red blood cells), leukocytes (white blood cells), and thrombocytes (platelets). By volume, red blood cells constitute about 45% of whole blood, plasma about 54%, and white cells only about 0.7%.

If blood is allowed to stand without the addition of an anticoagulating agent, red cells will clot. The resultant fluid (serum) can be decanted. If anticoagulants are added to a tube of fresh blood, plasma can subsequently be prepared by spinning the tube in a centrifuge until the blood cells fall to the bottom of the tube. The total volume of plasma in an average person is 2.7–3.0 L. It is essentially an aqueous solution containing 92% water, 8% blood plasma proteins, and trace amounts of other materials.

Serum is, in most respects, similar to plasma except that it does not contain soluble factors that lead to blood clotting. In this sense, blood serum is blood plasma without fibrinogen or the other clotting factors.

The proportion of blood volume that is occupied by red cells is referred to as the hematocrit. It ranges from 35 to 54% in blood from healthy adults, being higher in men than in women. Most drugs are not equally distributed between the subcompartments of blood; consequently, the concentration in serum or plasma may differ from that in whole blood. The knowledge of blood to plasma concentration ratios is mandatory when the whole blood to plasma or serum levels have to be compared.

Plasma and serum samples are useless in a case where the compounds involved are known to be concentrated in the erythrocytes, such as phenothiazines, phenytoin, salicylic acid, chlorthalidone or imipramine, among others. Drugs of abuse, which are the compounds of interest in this article, do not show affinity for red blood cells; consequently, the three types of blood samples can be indistinctly used in their analysis. Nevertheless, drug analysis in forensic toxicology cases is usually performed on whole blood, whereas serum or plasma is preferably used in clinical studies.

Dried Spot Blood Samples

Dried blood spot (DBS) samples are becoming a significant tool in forensic toxicology. The first paper on DBS analysis for

Table 1 Comparison between dried blood spot (DBS) samples with the conventional samples (whole blood, serum, and plasma)

	<i>Conventional samples</i>	<i>DBS</i>
Sampling method	Invasive	Less invasive
Storage	In freezer at -20°C	At room temperature ^a
Infection risk	High	Minimum
Sample volume	$>0.5 \text{ ml}$	$<100 \mu\text{l}$
Additional analysis	Possible	Not possible
Repetition of analysis	Possible	Not possible
Methods	Sensitive	Very sensitive

^aIn general, DBS samples may be stored at room temperature for many weeks, months, or years. However, samples that contain unstable compounds should be stored at a lower temperature in order to enhance stability.

the estimation of blood glucose concentration was published in 1913 by Bang; however, the most prominent use of DBS dates back to the early 1960s when Robert Guthrie developed an assay for the detection of phenylketonuria. Recently, these samples have been successfully applied for the detection of illicit drugs in forensic cases whenever qualitative information is sufficient.

The collection of DBS samples is normally conducted by pricking the finger, heel, or toe with a lancet, and the blood drops are then spotted onto preprinted circles, ideally one drop per spot, on specially manufactured paper. Touching the circle area should be avoided, especially before the blood is applied and has completely dried. The blood sample can also be applied with a calibrated pipette onto the sampling paper, thus avoiding potential sampling errors. It is very important to dry blood spots completely before storage or transportation. In general, a minimum of 2–3 h drying in an open space at room temperature is recommended. However, the drying time depends on the type of paper and the blood volume applied.

Thus, after drying, the DBS samples should be protected against humidity and moisture. Humidity indicator cards should be included in the storage package. DBS samples protected in this manner may be stored at room temperature for many weeks, months, or years, depending on the analyte stability. Nevertheless, samples that contain unstable compounds should be stored at a lower temperature in order to enhance stability.

DBS is a useful tool in forensic toxicology, but it has not replaced conventional whole blood, plasma, or serum samples. Although DBS offers a number of advantages over conventional matrices, as shown in Table 1, it presents some challenges before it can be applied in routine practice, particularly stability and being able to provide quantitative results.

Drug Monographs

Amphetamines

These drugs are sympathomimetic phenethylamine derivatives possessing central and peripheral stimulant activity. They are used in the treatment of narcolepsy and attention deficit hyperactivity disorder. Recreationally, they are abused to increase

alertness, relieve fatigue, control weight, treat mild depression, and for their intense euphoric effects, as well as psychedelic effects, as occurs with 3,4-methylenedioxymethamphetamine (ecstasy or MDMA), for example.

The most abused AP compounds are amphetamine itself (AP), methamphetamine (MAP), MDMA, and 3,4-methylenedioxymethamphetamine (MDA). They occur as structural isomers and stereoisomers. The S(+) or *d*-form possesses approximately three to four times the central activity of the isomer (enantiomer) R(−) or *l*-form. But enantiomers not only differ in pharmacological activity, but also have different pharmacokinetic properties. The *d*-enantiomer of both AP and MAP are metabolized more rapidly than the *l*-enantiomer. The half-life for the *d*-isomer is 11–13 h, compared with a 39% longer half-life for the *l*-isomer. Consequently, knowledge of the enantiomer proportion can be helpful in the interpretation of analytical data.

Blood concentrations can generally be used to distinguish therapeutic MAP use from abuse. Concentrations of 0.02–0.05 mg l^{−1} are typical for therapeutic use, but up to 0.2 mg l^{−1} have been found in some cases. Normal concentrations in recreational use are 0.01–2.5 mg l^{−1} (median 0.6 mg l^{−1}), thus overlapping therapeutic concentrations.

MAP is metabolized to AP (also active), *p*-hydroxyamphetamine and norephedrine (both inactive). Several other drugs are metabolized to AP and MAP and include benzphetamine, selegiline, and famprofazone. Peak plasma AP concentrations occur around 10 h after MAP use.

MDMA is metabolized to MDA with 65% of the dose excreted unchanged within 3 days. It is further metabolized to its 3-hydroxy-4-methoxy and 3,4-dihydroxy derivatives (HMA and HHA). Additional MDMA metabolites include 3-hydroxy-4-methoxymethamphetamine and 3,4-dihydroxymethamphetamine.

No clear correlation exists between MDMA blood concentrations and its effects. MDMA and MDA are the analytes detected in blood, with MDA concentrations typically only 5–10% of the corresponding MDMA concentrations. Higher MDA:MDMA ratios may indicate coadministration of MDA. Residual and unwanted effects are generally gone within 24 h although confusion, depression, and anxiety may last several weeks.

Cannabis

The plant *cannabis sativa* contains more than 60 cannabinoids or chemically related compounds, the most active of them being Δ⁹-tetrahydrocannabinol (THC). Other compounds present in the plant in significant amounts are cannabidiol and cannabitol.

Most of the cannabinoids are psychoactive substances that produce pleasant feelings, drowsiness, and a decrease in cognitive and psychomotor performance. At the same time, they increase cardiac rate, blood pressure, and body temperature. Naïve consumers can experience anxiety, paranoia, or panic after smoking cannabis.

Although cannabis is usually smoked as a cigarette, oral ingestion also does occur. The data relating to the absorption of THC is shown in Table 2. The wide range in the bioavailability (18–50%) after smoking is a consequence of the large interindividual variability occurring during smoking dynamics. After oral administration, THC is also well absorbed, but

peak plasma concentrations are much lower than after smoking and occurs much later.

Due to its fat solubility, THC is rapidly distributed into tissues and accumulates in adipose tissue. This distribution phase results in a rapid decline in blood plasma concentrations. The apparent half-life is ~1 h, but in frequent users, the terminal half-life can reach 3–13 days.

THC metabolism is complex, with over 20 metabolites identified. The two monohydroxy metabolites 11-hydroxy-Δ⁹-tetrahydrocannabinol (11-THC-OH) and 8-hydroxy-Δ⁹-tetrahydrocannabinol (8-THC-OH) are active, with the former exhibiting similar activity and pharmacokinetics to THC, while the latter is less potent. Further oxidation of 11-OH-THC produces the inactive metabolite 9-carboxy-Δ⁹-tetrahydrocannabinol (THC-COOH), which may be conjugated with glucuronic acid. Plasma THC concentrations generally fall below 5 ng ml^{−1} less than 3 h after smoking, while in occasional users, concentrations rapidly fall below limits of quantitation within 8–12 h. The terminal half-life of THC-COOH in plasma is ~2–5 days, and it can be detected during a period of 12 days in the case of frequent consumers and during a period of 6 days in the case of nonfrequent users, respectively.

Sometimes it is necessary to ascertain if the person was under the influence of cannabis. The duration of action of cannabis is usually short, and it is related more to blood THC concentrations than to THC-COOH concentrations. The peak effect is experienced about 15–30 min after smoking, and the pharmacological effects often last for only 2–4 h.

Mathematical models, based on the THC:THC-COOH concentration ratios, have been developed to estimate the time of marijuana exposure within a 95% confidence interval. Knowing this elapsed time can then be used to predict impairment in concurrent cognitive and psychomotor effects based on data in the published literature.

Cocaine

COC is one of the most potent of the naturally occurring central nervous system stimulants. It has been utilized in medicine as a local anesthetic and is still used in oral and nasal surgery. Recreationally, COC is used to increase alertness, relieve fatigue, feel strong, and be more decisive, and is abused for its intense euphoric effects.

The routes of administration of COC are different depending on the source of COC (leaves, sulfate salt, hydrochloride salt, and free base, known as crack), affecting not only its pharmacokinetic but also its pharmacological effects. COC is mainly inhaled through the nose (insufflation), but it is also smoked, used intravenously (i.v.), and even taken orally.

COC is rapidly absorbed following all the routes of administration. It is extensively metabolized to a variety of compounds: ~30–50% of COC is metabolized by hepatic esterases and plasma pseudocholinesterase to ecgonine methyl ester. Spontaneous nonenzymatic hydrolysis of another 30–40% results in benzoylecgonine. Both products are water soluble and inactive. Norcocaine is a very minor metabolite but is active and neurotoxic. The apparent half-life for COC is short, ~0.7–1.5 h, while the half-lives of benzoylecgonine and ecgonine methyl ester are 6–8 and 3–8 h, respectively.

Table 2 Absorption parameters of the main drugs of abuse and drugs used for medicinal purposes

Compound	Route	Dose (mg)	C_{max} (ng ml ⁻¹)	T_{max} (h)
Amphetamines				
AP	Oral	10	35	2
MAP	Oral	10	30	1
MDMA	Oral	125	236	2.4
Cocaine	Oral	17–48	11–149	0.4–2

Pentobarbital	i.v.	50	1180	0.08
Phenobarbital	Oral	30	700	

C_{max} , peak concentration; T_{max} , time to reach peak concentration; and i.v.: intravenous.

^aThe data of MAM and morphine are obtained after the intravenous administration of 200 mg of heroin.

Ethylbenzoylcegonine or cocaethylene, formed following concurrent ingestion of COC and alcohol, is also active and is equipotent to COC in blocking dopamine reuptake. Its metabolites are hepatotoxic.

During smoking of COC base (crack), anhydroecgonine methyl ester (AEME, methylecgonidine) is formed in large amounts as a pharmacologically active pyrolysis product of COC, and it is absorbed in the lungs. AEME is not produced when COC is snorted or used i.v.; consequently, it is a marker of COC smoking.

Typical concentrations in abuse range from 0 to 1 mg l⁻¹; however, concentrations up to 5 mg l⁻¹ and higher have been reported in surviving chronic consumers. After single doses of COC, plasma concentrations typically average 0.2–0.4 mg l⁻¹. Repeated doses of COC may result in concentrations of >0.75 mg l⁻¹.

The faster the absorption, the more intense and rapid the peak effect, but the duration of action is shorter. Injecting COC produces an effect within 15–30 s. Smoking crack produces an almost immediate intense effect, which can last 5–15 min. Similarly, snorting COC produces effects almost immediately, and the resulting peak may last 15–30 min.

Heroin

Heroin (3,6-diacetylmorphine) is a semisynthetic opioid drug synthesized from morphine. The routes of administration

are usually i.v. injection, subcutaneous injection, or nasal insufflation.

After administration, heroin is rapidly hydrolyzed by serum and liver esterases to 6-acetylmorphine (6AM) and then to morphine. Morphine undergoes glucuronidation into morphine-6-glucuronide (M6G) and morphine-3-glucuronide (M3G) by liver, kidney, and brain enzymes with an M6G:M3G ratio of ~0.15. Conjugation at the 6-hydroxyl position of morphine does not prevent binding to opioid receptors; hence, 6AM and M6G contribute to the narcotic effects of heroin, which has little affinity for opiate receptors itself.

Heroin blood levels decline very rapidly after i.v. drug administration and become undetectable after 10–40 min. Due to their short half-lives, heroin and 6AM are not usually found in blood samples, and their presence in blood indicates a very recent administration while morphine and morphine glucuronides are detected over a longer period of time.

Pharmacokinetic data of heroin, 6AM, and morphine are summarized in [Tables 2](#) and [3](#). Data on the M3G or M6G kinetics after heroin administration are scarce, mostly because in earlier times, it was assumed that the morphine glucuronides were not relevant for the pharmacodynamic action of heroin. As M6G passes the blood–brain barrier with more difficulty than morphine, only a significant accumulation of M6G causes a pharmacodynamic effect. M3G lacks intrinsic opioid activity. After heroin administration, the terminal half-lives of morphine glucuronides (M3G and M6G) range from

Table 3 Overview of pharmacokinetic parameters of the main drugs of abuse and drugs used for medicinal purposes

Compound	Half-life (h)	Clearance (ml min ⁻¹ kg ⁻¹)	B:P ratio	V _D (l kg ⁻¹)	Protein binding (%)
Amphetamines					
AP	4–30 ^a		0.80	3–5	15–42

Pentobarbital	20–30	0.3–0.5	1.07	0.5–1.0	65
Phenobarbital	48–144	0.06	1.07	0.5–0.6	50

B:P: blood to plasma concentration ratio; V_D: volume of distribution.

^aHalf-life of amphetamine is pH dependent.

2.0 to 6.4 h. The time to reach peak concentrations ranges from 0.7 to 5.1 h, which is comparable to the results obtained from controlled morphine pharmacokinetic studies. The half-lives of the morphine glucuronides do not depend on the route of administration.

Illegal heroin contains other opioids, one of them being acetylcodeine, which is present to the extent of 2–20% as a by-product and is not present in pharmaceutical preparations. Consequently, acetylcodeine is a useful marker to differentiate between legal and illegal heroin.

The development of tolerance to regular users makes interpretation of blood or plasma morphine concentrations extremely difficult.

Other Drugs

Lysergic acid diethylamide

LSD is an indole derivative. The *d*-isomer is one of the most potent hallucinogenic agents while the *l*-isomer is apparently inactive. LSD is an indirect serotonin antagonist, which produces sympathomimetic, parasympathomimetic, and neuromuscular effects (mydriasis, lacrimation, tachycardia, and tremor).

The oral route of administration is the most common, but nasal and parenteral routes can be used, as well. LSD undergoes extensive biotransformation via N-demethylation and hydroxylation. In addition to N-desmethyl-LSD and hydroxy-LSD, other metabolites are 2-oxo-LSD and 2-oxo-3-hydroxy-LSD, all of them being inactive. Hydroxylated metabolites undergo glucuronidation to form water-soluble

conjugates. The threshold toxic dose in humans has been reported to be 100–200 mg with associated blood concentrations of 2–30 ng ml⁻¹.

A common side effect of LSD is the unpredictable recurrence of hallucinations for weeks or months after the last dose. Hysterical behavior, hyperactivity, and life-threatening hyperthermia are exhibited in some cases.

The onset of effects is rapid, within 5–10 min; with psychosis evident after 15–20 min. Peak effects occur 30–90 min after dosing, and they decline after 4–6 h. The duration of effects may be 8–12 h.

Ketamine

Ketamine is primarily used in veterinary applications as a tranquilizer. It is also used as an anesthetic induction agent for diagnostic and surgical procedures in humans, prior to the administration of general anesthetics. Its recreational use is due to its psychedelic and dissociative effects.

The route of administration can be injection, snorting, oral ingestion, and rectal administration. In addition, and similarly to PCP, ketamine can be added to tobacco or marijuana cigarettes and smoked.

Ketamine is rapidly distributed into the brain and other highly perfused tissues. It is metabolized to at least two active metabolites: first by N-demethylation, to norketamine, which is then dehydrogenated to dehydronorketamine. Oral administration produces lower peak concentrations of ketamine, but increased amounts of the metabolites norketamine and dehydronorketamine. Norketamine produces depressant effects similar to those of ketamine. There are no significant

differences between the pharmacokinetic properties of the S-(+) and R-(-)-isomers.

There is no direct correlation between ketamine concentrations and behavior. Drowsiness, perceptual distortions, and intoxication may be dose related in a concentration ranging from 50 to 200 ng ml⁻¹, and analgesia begins at plasma concentrations of about 100 ng ml⁻¹.

Adverse reactions include hallucinations, delirium, nausea, vomiting, respiratory stimulation, or depression. The drug has been abused by medical personnel for its hallucinogenic effects.

The onset of effects is within seconds if smoked, 1–5 min if injected, 5–10 min if snorted, and 15–20 min if orally administered. The effects generally last 30–45 min after injection, 45–60 min if snorted, and 1–2 h following oral ingestion.

Phencyclidine

Phencyclidine or 1-(1-phenylcyclohexyl) piperidine (PCP) is a veterinary tranquilizer and, at the same time, a popular drug of abuse. It is structurally related to ketamine, and it acts as a hallucinogen, dissociative anesthetic, psychotomimetic, and sedative-hypnotic.

It is self-administered by different routes (i.v., nasal, oral), and it is well absorbed following all of them. It was first abused in the oral form, but later the smoked form gained popularity, in spite of ~50% of PCP in cigarette smoke being converted to an inactive thermal degradation product.

PCP binds with high affinity to sites located in the cortex and limbic structures of the brain. Due to its action on several systems, the physiological and behavioral effects of PCP are varied and depend on not only the dose, but also the route of administration and chronicity of consumption.

Metabolism undergoes oxidation and hydroxylation to at least two inactive metabolites, which are later conjugated with glucuronic acid.

There is no direct correlation between PCP concentration and the degree of intoxication (behavioral or physical findings). PCP causes sedation, nystagmus, hypertension, ataxia, agitation, combativeness, seizures, coma, and respiratory depression.

Long-term users of PCP report feeling the effects within 2–5 min after smoking, with the peak effect after 15–30 min and residual effects for 4–6 h, which can last up to 24 h in some cases. Long-term psychological effects are possible, and PCP may precipitate a psychotic reaction lasting a month or more that clinically appears like schizophrenia.

Abused Prescription Drugs

The difference between abuse and misuse is mainly based on the individual's intention or motivation. Drug abuse occurs when the medication is taken, usually at higher doses than prescribed, specifically in search of a pleasant or euphoric feeling; while misuse of a drug occurs when individuals are treating themselves, but not according to the directions of their health care providers.

Four major classes of drugs are mainly used for nonmedical purposes: (a) tranquilizers, such as benzodiazepines – including diazepam, alprazolam, etc. – and nonbenzodiazepines – zolpidem, zopiclone, etc.; (b) sedatives, especially barbiturates; (c) stimulants – AP, methylphenidate, and MAP; and (d) pain

relievers, particularly those containing opiates – hydrocodone, oxycodone, fentanyl, methadone etc.

Benzodiazepines

Benzodiazepines are among the most commonly abused prescribed drugs in forensic toxicology. Abuse is observed in two forms: persistent therapeutic use longer than generally recommended and illicit use, where the drug is self-administered without physician approval or supervision, which may involve use of high doses and clear indication of acute intoxication and impairment.

Benzodiazepines effect central depression on spinal reflexes, in part mediated by the brainstem reticular system. They are used as hypnotics since they have the ability to increase total sleep time. Cardiovascular effects are minimal, but heart rate is increased and cardiac output decreased. They are used recreationally as sedatives or to enhance the effects of alcohol or opioids.

All benzodiazepines demonstrate a wide range of absorption rates when orally administered and reach peak plasma concentrations within a few hours of oral administration. For example, single oral doses of 10 mg result in diazepam concentrations of 200–600 ng ml⁻¹ at 0.5–2 h, while chronic doses of 30 mg produce steady state diazepam concentrations of 700–1500 ng ml⁻¹ and nordiazepam concentrations of 350–530 ng ml⁻¹.

There are significant differences in the bioavailability of the different compounds. For instance, diazepam and alprazolam have bioavailabilities of 100 and 90%, respectively; while triazolam bioavailability is around 40%.

The half-lives of benzodiazepines vary enormously, from 3 h for triazolam to over two days for nordiazepam. Benzodiazepines are extensively metabolized producing multiple metabolites, many of which share common pathways. The most common metabolites are hydroxylated and dealkylated analogs, which are often pharmacologically active. Diazepam is metabolized to nordiazepam, which is an active metabolite with a half-life of 40–99 h. Temazepam and oxazepam are minor active metabolites of diazepam.

Due to changing responses with repeated use and variability in response between persons, blood concentrations will not provide a good indication of likely behavioral effects. Additionally, the long half-life of some benzodiazepines may cause accumulation to occur with repeated use. Blood concentrations may be several-fold higher after chronic use compared to single use, and there are often significant increases in blood levels in the elderly. Therapeutic blood concentrations of diazepam typically range from 0.1 to 1.0 ng ml⁻¹. Plasma concentrations of 0.3–0.4 ng ml⁻¹ are recommended for anxiolytic effects. Higher concentrations might suggest misuse or abuse.

In general, there is poor correlation between blood half-life of benzodiazepines and duration of action. In practice, low-potency benzodiazepines have a shorter duration of action compared with their half-lives, and high-potency benzodiazepines have a longer duration of action than predicted by their half-lives.

Nonbenzodiazepine drugs: zolpidem and zopiclone

Zolpidem and zopiclone are nonbenzodiazepine hypnotics used in short-term treatment of insomnia.

Zolpidem is an imidazopyridine derivative used as a hypnotic agent. In spite of its chemical structure being unrelated to benzodiazepines, it is, nevertheless, a GABAA receptor agonist and shares some of the pharmacological properties of benzodiazepines. Zolpidem shortens sleep latency and prolongs total sleep time in patients with insomnia but has little effect on the stages of sleep in normal subjects. It also has weak anticonvulsant properties.

Zolpidem is absorbed readily from the gastrointestinal tract and then is converted to inactive metabolites by oxidation and phenolic hydroxylation. Pharmacokinetic data is summarized in **Tables 2** and **3**.

Zopiclone is a cyclopyrrolone derivative, which has been clinically used as a hypnotic agent. It is metabolized via N-demethylation, N-oxidation, and ester hydrolysis. The N-oxide has some pharmacological activity.

Adverse effects after zolpidem and zopiclone consumption include dizziness, amnesia, headache, and nausea. Hallucinations may occur, especially in patients taking zolpidem together with antidepressant medication.

Barbiturates

Barbiturates exert hypnotic, sedative, anxiolytic, anticonvulsant, and anesthetic properties. The use of barbiturates as sedative-hypnotic agents has largely been replaced by the benzodiazepines; nevertheless, they maintain an important role as anticonvulsant and anesthetic drugs.

When utilized as sedative-hypnotics, barbiturates are orally administered, and they are rapidly and completely absorbed

when used for the induction and maintenance of anesthesia. In the treatment of status epilepticus, they are administered i.v.

Barbiturates are generally widely distributed throughout the body, and they are metabolized by oxidation and conjugation. The oxidation of substituents at the C5 position is the most important factor in terminating pharmacological activity.

Glossary

Cut-off Concentration above which a positive result is reported.

pH The logarithm of the concentration of hydrogen ions of water; pH 7 refers to a neutral situation.

pK_a The pH at which half of the molecule exists in ionized form.

Introduction

Some parts of the community are known to misuse legal drugs, for example, sedatives and pain-relieving medications, for obtaining relief from pain and in case of ill health, while other persons use illegal drugs such as cannabis (marijuana), cocaine, and one or more of the amphetamines for recreational reasons. Persons who use drugs on a long-term basis have often increased their dose due to their developing tolerance and have also become dependent on them, making it very difficult to stop using them. This pattern of use leads to a pattern of addiction that not only controls their lives but is also associated with adverse symptoms and drug-seeking behaviors. Impaired cognition, and poorer reaction times and coordination skills can lead to an increased accident risk, whether it is at the workplace or while driving a motorized vehicle. The ability to screen persons rapidly for potential use of impairing drugs has become a significant safety issue.

For many years, drug tests using urine have been performed to determine if one or more of the targeted drugs of abuse are present in the body. For the most part, urine testing only provides information on past use, usually within 1–3 days of collection and can reveal very little about drugs being actually present in blood at the time of collection. While urine is still a useful specimen, there has been a trend to use oral fluid to test for drug use.

Drugs can be present in oral fluid, which can be collected without great inconvenience to the subject, whereas urine can be collected only in toilet facilities, and blood requires venepuncture by a specially trained person, which may be regarded as invasive by the subject when there may not be actual evidence of drug use by him/her.

This article provides an overview of the use of oral fluid in forensic toxicology.

What is Oral Fluid?

Oral fluid is sometimes called saliva, but it is actually a composite of a number of fluids (including saliva) secreted into the oral cavity. These are secreted primarily by three glands: the parotid, submaxillary, and sublingual glands, as well as by other smaller glands. Oral fluid is of variable viscosity and

pH depending on a range of physiological variables and can vary in flow from almost zero to several milliliters per minute.

The mechanism of drug transport from blood to oral fluid is largely by passive diffusion to non-protein bound and non-ionized molecules with a low molecular weight. Oral fluid contains predominantly the parent drug because the higher lipid solubility of parent drugs allows passive diffusion. Consequently, drugs with high lipid solubility tend to have higher concentrations. There are also differences in the concentration of drugs in the various secretions, and as these secretions are dependent on variable factors, the overall concentration of drug is not easy to predict.

Collection of Oral fluid

The most common way to collect fluids in the mouth is the use of a material which absorbs fluids on and around the tongue similar to a cotton bud. This is allowed to be in the mouth for a few to several minutes until sufficient fluid has been absorbed. This is then added to a diluent (aqueous buffered solution) that dilutes the oral fluid and makes it more amenable to analysis.

Neat oral fluid is also used. This involves expectoration or spitting a sample into a plain collection tube. While this provides neat (undiluted) oral fluid, it is relatively viscous and can make accurate sampling difficult. As it may also be contaminated with food and other debris from the mouth, it will, therefore, require filtration or centrifugation.

If only initial testing is required, a simple swab of fluid on the tongue or the inside of the cheek can provide sufficient sample for a rapid drug test. However, if this test is positive, there is no oral fluid for any second or confirmatory test. This will then require a second collection.

Hunger will stimulate production of oral fluids, while inadequate hydration and certain drugs such as the amphetamines and cannabis can reduce production.

When oral fluid content and/or flow is suboptimal, it will require a much longer collection time to collect a small volume of oral fluid. It may take several minutes to collect <1 ml of oral fluid.

One of the potential pitfalls related to the use of absorbent swabs in the collection of oral fluid is that there may be some loss of drug on the swab itself. There have been many examples

in the past of severe losses of drug on this surface leading to false-negative results (i.e., drug was present, but the test was negative). Hence, it is good practice to test for recovery of drugs as quickly as possible after use and ensure that the testing process is sufficiently reliable and sensitive.

Factors Affecting Drug Presence in Oral Fluids

Drugs in oral fluid are for the most part in equilibrium with drug in the blood, particularly drug in blood plasma that is not bound to proteins (so-called free fraction). The concentration of drug in oral fluid is also dependent on the respective pH of the two fluids and the pK_a of the drug in question.

For example, the oral fluid to plasma concentration ratio (O/P) for a basic drug with pK_a and free fraction from protein binding in plasma (f_p) and oral fluid (f_o), at the respective pH of the fluids (pH_o and pH_p) is given by the following equation:

$$O/P = \frac{1 + 10^{(pH_o - pK_a)}}{1 + 10^{(pH_p - pK_a)}} \times \frac{f_p}{f_o}$$

Drugs with high pK_a are usually unionized at pH around 7 (e.g., amphetamines) and will, therefore, have a relatively high concentration in oral fluid compared to drugs with a low pK_a (i.e., acidic drugs such as the benzodiazepines).

The normal pH of oral fluids is between 6.2 and 7.4; however, this can vary depending on time of day, food, age, health, and the use of certain drugs. Oral fluid production is stimulated by the use of lollies that contain citric acid, chewing gum, or other agents. When this occurs, the concentration of basic drugs such as cocaine, codeine (and probably other opiates), and the amphetamines drops substantially due to the lowering of the pH affecting the equilibrium between oral fluid and plasma.

In practice, the oral fluid/plasma (blood) concentration ratio is not constant because the pH of oral fluid changes and for some drugs, local absorption in the mucosa of the oral cavity results in oral fluid concentrations that are higher than expected. This latter effect is particularly pronounced for Δ^9 -tetrahydrocannabinol (THC) as the drug is usually smoked and being fat soluble, it is absorbed into the mucosal membranes and slowly released over several hours. However, for some drugs, there is a weak correlation between a blood/plasma concentration and an oral fluid concentration and the degree of impairment. Hence oral fluid is favored as alternative for blood/plasma since it is much more likely to indicate recent use and likely impairment whereas urine does not have this association. **Table 1** provides an indication of the oral fluid to blood concentration ratios for selected drugs of abuse.

A number of drugs affect the secretion of oral fluid including amphetamines, sedating antihistamines, antipsychotic drugs, anticholinergic drugs, and a number of antidepressants, and cannabis. There are a few drugs that increase flow including β_2 bronchostimulants (e.g., salbutamol).

Mouth rinsing with water will reduce the concentration temporarily by leaching out some drug in the mucous membranes, but the equilibrium will reestablish with 10–15 min. The use of commercial products designed to act as adulterants (e.g., mouth washes) have been shown to have little effect after 30 min.

Table 1 Average oral fluid to blood concentration ratios for selected drugs of abuse

<i>Drug (type)</i>	<i>Average oral fluid to blood concentration ratio</i>
Alcohol (ethanol)	1.07
Amphetamines (e.g., methamphetamine, amphetamine, 3,4-methylenedioxymethamphetamine (MDMA))	2–20
Barbiturates (e.g., amobarbital, pentobarbital)	0.1–0.5
Benzodiazepines (e.g., alprazolam, diazepam)	<0.05
Cocaine	2–5
Opiates (e.g., codeine, morphine, methadone)	2–5
Tetrahydrocannabinol (THC)	10–20

The average ratios are indicative figures and will change depending on a number of factors.

Applications of Oral Fluid Drug Testing

One of the largest applications for oral fluid has been testing drivers suspected of using drugs. In Australia, for example, most states and territories have widespread mass screening programs to test drivers at the roadside without cause in order to deter drivers using illicit drugs, particularly methamphetamine, ecstasy, and cannabis. Similar testing is being trialed in Europe. In this process, the initial test is a swipe on the tongue while the driver is still behind the steering wheel after having passed a breath test for alcohol. If this test is positive for one of the targeted drug classes, the police require the driver to leave his/her vehicle and submit to a collection of oral fluid at a neighboring facility, usually a specially outfitted van or bus parked nearby. If a further test for these drug classes is positive using another screening device, the remaining specimen is sent to a forensic laboratory for confirmatory testing, and the driver is not allowed to continue driving. A confirmed positive results in a penalty.

Oral fluid testing is also used at workplaces in safety critical industries such as transportation (road, rail, and aviation), mining, construction, and petrochemical industries. It can also be used on prisoners and on persons suspected of a crime and who are also suspected of being under the influence of a drug.

However, it should not be seen as a replacement or a substitute for urine testing. Urine testing can usually provide a longer window of detection than oral fluid, although for some drugs with a high oral fluid to blood ratio, the detection window may be similar if low detection limits in oral fluid are used. It is recommended that detection limits in oral fluid, usually referred to as cut-offs, are sufficiently low to detect reasonable use of drug but not too low to detect beyond a time when a person might be adversely affected by the drug.

For example, confirmatory testing limits of THC in oral fluid of 10 ng ml^{-1} reflect use of cannabis for several hours, whereas lowering the cut-off to 2 ng ml^{-1} may allow detection for at least 24 h.

Oral fluid has been used in clinical settings to monitor use of therapeutic drugs. These have been used for some anticonvulsant drugs, digoxin, methadone, some anticancer drugs, and a number of steroids. Even ethanol (alcohol) can be measured in oral fluid as a quick screening method if breath testing is not possible.

Analytical Testing Methods

Field testing, point-of-care testing, or on-site testing is commonly employed. A number of devices are available for such use and include handheld cartridges for visual assessment of test results to small instruments that automate the process and can provide an electronic reading of the test result. At this point, there is no consistency in the specifications applied to these devices including sensitivity and detection limit (or cut-off), and specificity. This means that at the present moment, there is no easy way to assess the performance of these devices or cartridges without personal evaluation.

Currently, these devices are largely based on lateral flow immunoassay; hence, they will not detect all members of a drug class equally. For example, for the amphetamine and benzodiazepine classes the required sensitivities will be different for the various members of these classes and their individual concentrations are quite different to that of blood. For example, benzodiazepines have much lower concentrations in oral fluid compared to blood and only the lower potency members can be detected in oral fluid with any frequency.

Laboratory-based testing using commercial kits based on enzyme-linked immunosorbent assay technology is much more reliable than on-site testing and will produce a lower false-positive and false-negative rate. Laboratory testing can be done under more controlled conditions including temperature control and use of appropriate standards and quality controls.

All initial tests need to be confirmed by mass spectral methods. These may include gas chromatography–mass spectrometry or liquid chromatography–mass spectrometry. Numerous methods have been published, some in which multiple analytes can be confirmed in one analytical schema. The choice of method is largely dependent on its availability in a laboratory and the sample volume. Low sample volumes

(under 0.5 ml) may require the more sensitive tandem mass spectrometry methods.

Unfortunately, there are no agreed laboratory methods for this form of testing with each jurisdiction applying different cut-off concentrations. This is largely reflected by the relative immaturity of this form of testing. This is likely to change as experience in the use of this specimen in forensic toxicology increases.

WHO World Health Organization

Introduction

A drug-facilitated crime (DFC) takes place when illegal activity occurs against a person, while they are incapacitated because of the effects of a drug or drugs in their body. If the literature on this topic is searched, the majority of resulting scientific papers and web sites refer solely to drug-facilitated sexual assault (DFSA), a crime that is very much at the forefront of the media. However, DFCs include a wide range of offenses, including blackmail, theft, and extortion, and in some cases, may involve combinations of various crimes. The administration of drugs to dependants in order to sedate them is also considered a DFC.

Specific advertizing campaigns now exist as a deterrent to young adults with a focus on the overuse of alcohol or binge drinking on nights out. Despite media hype that the pub and club scenes are rife with drink-drug spiking, the majority of journal articles reviewing the types of drug found in DFSA cases conclude that in the majority of cases, alcohol is the main drug found in alleged victims. This, however, does not negate the fact that in some cases drugs are involved.

Definitions

DFC or DFSA is a term used to refer to all forms of non-consensual activity undertaken when the victim of the activity is profoundly intoxicated. Legally, there are three main ways by which the intoxication can occur as follows:

1. self ingestion of an incapacitating or disinhibiting substance;
2. forced or covert administration of an incapacitating or disinhibiting substance;
3. self and forced or covert administration of an incapacitating or disinhibiting substance.

The incapacitating or disinhibiting drugs may be illicit or medicinal drugs, and in many cases, a combination of drug types and alcohol are found. Operation Matisse has recommended that DFSA is redefined as either Proactive DFSA, where the victims are drugged either by force or covertly, or Opportunistic DFSA, where the victims are intoxicated by their own actions.

Drug-Facilitated Sexual Assault

Sexual assaults in general are underreported to the authorities. The British Crime Survey (2001) reported that only 12% of subjects who admitted undergoing a serious sexual assault reported the crime to the police. In 2004, there were 2689 prosecution of rape with less than 30% of these cases resulting in conviction. The World Health Organization (WHO) has evaluated the use of drugs by not only victims of crime but also the perpetrator of these crimes. A strong link between interpersonal violence (including sexual offenses) and drug use has been shown.

Of all subjects who stated that they had been sexually assaulted vaginally or anally, 5% stated that they had been drugged, and 15% stated that they had been unable to consent because of alcohol intoxication. For other penetrative offenses, 6% stated that they had been assaulted while drugged and 17% of them had been unable to give consent because of alcohol intoxication. Regardless of the date, country, or governing body, who has produced these statistics, the picture is the same worldwide and DFSA is a crime that warrants investment at a government level.

The low-reporting rates for sexual offenses are further decreased in DFCs because of feelings of guilt or shame due to self-administered drugs and alcohol, particularly, when the drug ingestion is illicit; confusion and uncertainty because of memory impairment due to the drugs' effects regarding what happened; and reluctance to make accusations without personal knowledge, or memory, of the circumstances leading to the assault.

Typical Drugs in DFC

The types of drug found or utilized in DFC are varied in their effects and cover the whole range of drugs investigated in a Forensic Toxicology laboratory. Although one might think that DFC drugs should be central nervous system (CNS) depressant in nature, CNS stimulants are also encountered. In general, CNS depressants slow down the activity of the CNS and the transmission of messages going between the brain and the body, and CNS stimulants speed these processes up and may contribute to the impairment from a CNS depressant. Both types of drugs can have fatal consequences if misused or combined with other drugs or alcohol.

Drugs that are taken by the victim himself or herself tend to be disinhibiting in nature, resulting in a fortuitous or opportunistic event, where the potential victim is taken advantage. Both CNS stimulants and depressants are found in these types of cases. Some substances with CNS stimulant activity, including amphetamine-type stimulants, may cause disinhibition, leading to inappropriate risk-taking behavior resulting in non-consensual sexual activity.

In contrast, the type of drug forced or administered to a potential victim is more likely to be incapacitating in nature and likely to be preplanned. These drugs are more likely to be CNS depressants and have effects as noted below.

The ideal candidate drugs for DFC are likely to exhibit some or all of the following properties: odorless, colorless, easily dissolvable in liquid, amnesic, fast acting at low doses, short lived, producing disinhibition, and relaxation to incapacitate the victim.

The amnesic effect of candidate drugs is an important property, as this results in delayed presentation and therefore loss of associated evidence. In some cases, anterograde amnesia may be so profound that the victim is never aware of the events that took place and therefore will never report the crime.

The high potency, low dose, and short half-life of these drugs result in further complications to the investigation, as even if the victim does present within a reasonable time frame, some of the drugs will no longer be present or detectable in the toxicological samples taken for analysis.

Within the media in the previous decade, there have been two favorite drugs that may or may not have been successfully utilized in these crimes. These two drugs are discussed in more detail below along with potential issues relating to their detection in biological samples.

Gammahydroxybutyrate

The first of the drugs and possibly the most complicated is gammahydroxybutyrate (GHB). One of the reasons why GHB is problematic in terms of toxicology is that it occurs naturally in the brain. It is a precursor and metabolite of gamma-aminobutyric acid (GABA). As a drug, it was first manufactured in the 1960s, and it has been used as a general anesthetic, as a sleep aid, and in the treatment of alcoholism. In the 1980s, it was marketed as a supplement for body builders, as it increases the episodic secretion of growth hormone. More recently, it is being prescribed for sleep disorders, including narcolepsy. For many years, it has been popular on the club scene, because of production of feelings of mild euphoria and alcohol-like symptoms. GHB is now illegal in most countries because of its unwanted side effects and allegations of use in DFC.

As a DFC drug, GHB ticks many of the boxes, it is odorless, colorless, quite water soluble, and thereby can be surreptitiously slipped into a drink. It also acts fast with a relative short duration of action. In solution, it is mildly saline and therefore has a slightly salty taste; however, if diluted into the drink of a subject, it is possible that they would not notice this.

As with other drugs, the effects (and side effects) of GHB depend on the weight, height, and health of the subject on whether they have other drugs or alcohol in their system and whether they have used GHB before. GHB has a steep dose response curve and therefore small increases in dose

could have a significant effect on the intensity of the effects and the onset of CNS depression. This makes it particularly dangerous to the naive user, particularly, when it has been given to them without their knowledge.

The reported effects of GHB include mild euphoria (at low doses), amnesia, intoxication, drowsiness, dizziness, nausea, visual hallucinations (at higher doses), hypotension, bradycardia, severe respiratory depression, and possibility of coma and death if too high a dose is taken or given.

Although GHB has been reported to have a short half-life of approximately 30–50 min, it is now believed that like ethanol, GHB has no true half-life and exhibits zero-order kinetics with a proposed elimination rate of 18 mg l^{-1} . It does, however, like ethanol, have a terminal half-life that fits with the previously denoted half-life. This would in part account for the short detection half-life, which is also complicated by the fact the all blood and urine samples contain GHB because of the endogenous presence of GHB. GHB levels of up to 490 mg l^{-1} have been reported for Hospital Emergency patients. At this level, GHB would be detected for over 24 h; however, only a tolerant individual would survive this.

Owing to the endogenous nature of GHB, laboratories are required to use cut-offs for reporting positive results. Endogenous levels in the living are below 10 mg l^{-1} in blood and recommended cutoff values are 10 mg l^{-1} for blood and 5 mg l^{-1} for urine. A further compounding issue with GHB is that its metabolites are other endogenous compounds that culminate in the production of water and carbon monoxide. Thus, proof of use via metabolite detection in urine is not an option.

Flunitrazepam

The second commonly noted DFC drug is the benzodiazepine flunitrazepam. As noted above, flunitrazepam has a reasonable half-life (16–35 h); however, it is effective at low doses. Flunitrazepam is characterized as a short-acting benzodiazepine. Benzodiazepines are sedative-hypnotic drugs that are used to treat anxiety, insomnia and sleep disorders, and seizure disorders. Some of them are also used as skeletal-muscle relaxants as premedication for hospital procedures. Flunitrazepam is ten times more potent than diazepam, and while commonly prescribed for anxiety and sleep disorders in Europe, Latin America, and elsewhere, it was never approved for use or sale in the United States. In the UK, it is now classified as a Schedule 3 drug under the Misuse of Drugs Act 1971 meaning that it, along with temazepam, is more restricted in terms of prescription than other benzodiazepines.

Effects and side effects of flunitrazepam include disinhibition, amnesia and memory impairment, excitability or aggressive behavior, decreased blood pressure, drowsiness, visual disturbances, lack of consciousness, dizziness, confusion, and stomach disturbances. As with GHB, many of the boxes associated with 'good' DFC drugs are ticked. The drug is odorless, tasteless, and colorless; however, following allegations of its use in DFC cases, the producers introduced a blue dye into the tablets and lowered the tablet strength to 1 mg.

Despite the allegations of its use in DFCs when statistics from toxicology laboratories across the world are evaluated, other benzodiazepines are much more commonly

encountered, for example, in a UK study, there were 84 cases where benzodiazepines were detected and reported; in a Canadian study, 20 cases were reported; and in a Swedish study, 147 cases were reported. In the UK and Canadian studies, no flunitrazepam was detected; however, in the Swedish study, flunitrazepam was detected in seven cases and metabolites of flunitrazepam was detected in a further seven cases. A further case from Japan in 2006 found the primary metabolite of flunitrazepam, namely, 7-amino-flunitrazepam to be present in the urine of the victim, which had been collected 24 h post-ingestion. The victim claimed loss of memory and memory impairment for a period of approximately 19 h post-ingestion.

More recently, single-dose studies for flunitrazepam in the urine of 16 volunteers have indicated that metabolites can be detected up to and exceeding 10 days post dose. This advocates the use of urinalysis in late-reporting DFC cases. The study also warns against reliance on immunoassay screening in DFC. Guidelines on recommended maximum cutoff concentrations in urine have been issued by the Society of Forensic Toxicologists (SOFT) for both parent drugs and metabolites. The recommendation for metabolite testing also highlights the need for hydrolysis, in particular, with drugs that form conjugated metabolites (e.g., benzodiazepines).

Alcohol in DFC

By far, alcohol is the most commonly encountered drug in all DFSA studies. The percentage of cases in which alcohol was detected ranged from 37% to 69%. The main reason for the prevalence of alcohol is its wide availability, its acceptability in society, and the fact that most cases of alleged DFSA occur when the victim is socializing. In studies, up to 77% of the evaluated cases claimed to have consumed alcohol.

The effects of alcohol are well documented and understood as is its pharmacology. Unlike other drugs measured in toxicological samples, it is possible to extrapolate back from the results of a blood-alcohol result and estimate the level of alcohol, which would have been present at the time of the offense. This is an extremely important piece of forensic evidence as a reasonable opinion regarding the likelihood of the victim being unable to provide informed consent is possible. It has been estimated that the average alcohol concentration in casework is around 220 mg% with a range of <100 to >400 mg%. This raises the issue of capacity to give informed consent and the legal consequences of this.

In 2006, the association of alcohol-induced blackouts and grayouts to blood-alcohol concentrations was evaluated. This information is useful in DFC as knowledge of the likelihood of an amnesic episode is a supportive courtroom tool. If a subject has a blood alcohol of 305 mg% or above, they are more likely to be telling the truth regarding a blackout.

The Role of the Forensic Medical Examiner/Forensic Nurse in DFC Cases

When an alleged victim does report to the police, it is important that forensic protocols be strictly adhered to in order that if a

prosecution is brought forward, the forensic evidence is suitable for admission to court. Once the subject has undergone initial interview, a qualified medic (medical examiner, forensic nurse, or equivalent) is introduced to them in order to evaluate them and collect any evidence that may be present depending on the crime that has been committed. If the subject appears to be intoxicated or makes an allegation of drink spiking, it is of upmost importance to obtain blood and urine samples as soon as possible following protocols for whatever jurisdiction the subject is in. Failure to take these samples in a timely manner may result in insufficient evidence being available for prosecution.

In sexual assault cases, the subject will be asked to consent to a full forensic examination, and therefore consent is required before this can commence. If the examiner feels that the subject is under the influence of drugs or alcohol, a sleeping off period may be required until the examiner feels that the subject is consenting of free will. As with drug driving, the examiner may form an opinion as to what type of drugs are in the system of the subject at the time of the examination. This may assist the laboratory in their analysis, particularly where samples are time limited, as is the case with certain drugs even if the subject reports the day after the alleged offense.

In other types of DFC, although a full body examination may not be required, there may be other types of evidence that can be collected, including hairs and fibers and control samples from the subject for elimination purposes. The same criteria regarding the collection of samples for toxicological analysis apply, and these samples must be collected as soon as possible after the alleged crime has been reported.

Samples Types in DFC

In many jurisdictions, it still remains a standard practice to only take urine samples in DFC cases, particularly, if the crime is reported after more than 24 h have passed. With urine, 'at time' intoxication is impossible to prove and if drugs are still in the system, the expert testimony of the police officers and medical staff who interacted with the alleged victim will be critical. Although toxicological evidence is still required on urine, the interpretation provided by the toxicologist for drugs will be limited.

However, many drugs, including prescription and illicit drugs, may still remain in the blood stream for up to and exceeding 24 h. This is dependent on the plasma elimination half-life of the drug. In addition, many of the drugs utilized have active metabolites that may have longer half-lives and therefore prolong the effects of the drug. All drugs, however, have metabolites and an understanding of the metabolic profile of a drug is an important consideration for a reporting forensic toxicologist and for toxicology laboratories when they are designing analytical protocols. For example, diazepam has a plasma half-life of 16–40 h, but its primary metabolite desmethyldiazepam has a half-life of 40–100 h. The metabolite is therefore detected not only for a longer period of time but also shows a much higher degree of interindividual variation. A selection of the drugs detected in alleged cases of sexual assault in the UK between January 2000 and December 2003

Table 1 Selected DFC drugs from UK casework and their half-lives

<i>Drugs (number of cases/spikings)</i>	<i>Half-life [range (mean)]</i>	<i>Drugs (number of cases/spikings)</i>	<i>Half-life [range (mean)]</i>
Diazepam (44/3)	20–40 h	Dihydrocodeine	~4 h
Temazepam (24/6)	8–15 h	Methadone	10–25 h (15 h)
Lorazepam (5/1)	9–24 h (14 h)	Amitriptyline	9–36 h
Nitrazepam (4/1)	18–38 h (28 h)	Mirtazapine	20–40 h
Chlordiazepoxide (3)	5–30 h (15 h)	Prochlorperazine	8–16 h (12 h)
Lormetazepam (1/1)	~10 h	Promethazine	10–15 h
Flurazepam	2–3 h ^a	Thioridazine	10–36 h
Clobazam	10–58 h (25 h)	Phenobarbitone	90–100 h
Zopiclone	3.5–6.5 h	MDMA (47/3)	6–7 h
GHB	20–50 min (18 mg l ⁻¹)	Cannabis (260)	~2 h
Chlorpheniramine	(2–43 h) ^b	Cocaine (110)	0.7–1.5 h
Diphenhydramine	2.4–9.3 h	Amphetamine (23)	4–8 h
Codeine/morphine	2–4 h	Heroin (12)	2–3 h (morphine)
Dextropropoxyphene	8–24 h (15 h)	Ketamine (3)	2–3 h

^a*N*-Desalkylflurazepam has a half-life of 2–5 days.

^bShorter half-life in children.

are summarized in Table 1 along with their usual elimination half-lives.

Recently, the United Nations Office of Drugs and Crime (UNODC) has produced guidelines for the forensic analysis of drugs in DFC, including advice on the timely collection of blood, urine, and hair samples; instrumentation requirements; and interpretation of results.

Although as noted above, some of the drugs have long half-lives, the dose required for effect also has to be taken into consideration when evaluating the toxicological evidence. In addition, drugs with similar half-lives need not be detected for the same length of time because of differences in dosing and in other pharmacological parameters including volume of distribution. An example of this regarding parent drugs is for diazepam and flunitrazepam. Diazepam has a half-life of between 16 and 40 h, and flunitrazepam has a half life of 20–40 h. The half-lives of the drugs are comparable. However, diazepam is usually dosed at 5–20 mg, whereas flunitrazepam is effective at doses of only 1–2 mg meaning a method for the therapeutic detection of flunitrazepam needs to be much more sensitive than a method for diazepam.

Detection of drugs in blood close to the time of the offense gives the best forensic evidence that a DFC may have taken place; however, this on its own cannot prove that a crime has occurred. Toxicological evidence is only a small part of a much bigger picture, which the law enforcement agencies and forensic scientists must put together in order secure a conviction, if it is to be shown that a crime has been committed.

In later reporting cases, that is, cases reporting more than 48 h, although there may be drugs remaining in the subject's system, for most single-dose drugs, the levels remaining are likely to be below the detection limits of many laboratories, and therefore urine becomes the primary evidential sample. It is critical here that suitable sample preparation techniques are carried out, including hydrolysis for laboratories that do not carry out direct analyses of phase II metabolites (glucuronides and sulfates). The hydrolysis process cleaves the drug or metabolite from its conjugate allowing for direct analysis of the total drug or metabolite present in the sample.

In DFC cases, this is particularly important for urinalysis of benzodiazepines.

The final sample that must be included in any discussion of DFC is hair. By their very nature, DFCs warrant hair analysis as in many cases reporting of the crime is late and conventional samples are of little or no use. Even in cases where the victim reports within 24 h of the offense, hair samples must be considered.

For hair analysis, the reporting of DFCs can be classified into three categories: immediate (within 24 h), intermediate (up to 1 week), and delayed (more than 1 week). In immediate cases, a hair sample can be taken by the medic present at the initial evaluation. This is particularly important where GHB is suspected by the victim or as a result of the initial enquiry. Assuming that all other toxicological tests are negative, this sample, along with a second sample taken 4 weeks after the initial sample, should be tested for GHB. The first sample acts as a control as GHB is an endogenous drug and endogenous levels vary from person to person with reported endogenous GHB levels from 0.35 to 1.86 ng mg⁻¹. The second sample can therefore be compared to this to evaluate the presence of GHB in this sample. The UNODC guidelines state that a hair sample should be obtained at least 4 weeks after the alleged offense to ensure any drug ingested at the time of the offense is cleared from the scalp are before collection.

In intermediate cases, again the first sample acts as a control for GHB. Hair specimens in living persons are taken by cutting close to skin at the vertex region of the scalp. As newly forming hairs take 7–10 days to reach the surface of the scalp, samples taken before 1 week post incident should not contain the drugs ingested at the time of the incident.

Drugs are incorporated into hair directly from the blood stream or from the sweat, sebaceous, and apocrine glands around the hair follicle. Thus, any drug that is present in the blood should be detectable in hair. Factors affecting the detectability of the drugs include the physicochemical properties of the drug, drug treatments (e.g., bleaching and dying), hygienic washing, the amount of drug ingested, and the time from ingestion to sample collection.

A controlled study to evaluate if GHB could be detected in hair following a single exposure showed that it was possible to determine an elevated level of GHB in the hair of the subject corresponding to the time of ingestion using 3 mm segments of hair. Similarly, documented exposure to GHB via hair analysis has since been shown and highlights the importance of a control sample when GHB ingestion is suspected.

The third category of hair is not as useful for the analysis of GHB unless enough segments of hair are available in order to evaluate the baseline level of GHB in the individual's hair. Hair in these cases is the main sample that can be utilized in order to indicate ingestion of a drug around the time of the offense. However, for all drugs that have been administered as a single dose, there is a risk of washout, and therefore the evidential value of hair is decreased. Where a drug is detected, because of interindividual variation in the growth rate, the longer the time lapse between incident and hair collection the wider the estimated time of a positive result will be.

Controlled studies to evaluate the detectability of single exposure to a drug are of paramount importance in this area of forensic toxicology. Such reports exist for a variety of drugs, including GHB, flunitrazepam, clonazepam, diazepam, alprazolam, triazolam, ketamine, and a variety of metabolites. However, the real challenge lies in the detection of single exposures to drugs, where the target drug is unknown. Several case studies regarding this are available, and the types of cases discussed include sexual assault, drink spiking, robbery, poisoning, and child neglect cases. The results indicated that the majority of drugs utilized were sedative in nature, including benzodiazepines (flunitrazepam, lorazepam, alprazolam, clonazepam, and bromazepam); GHB; zolpidem; and antidepressant, including citalopram and methadone. The only stimulant drug detected was 3,4-methylenedioxymethylamphetamine (MDMA) that fits in the category of disinhibiting CNS stimulants discussed above.

Analytical Issues in DFC

The investigation of a DFC should involve a full toxicological investigation. Screening techniques for the full range of drugs of abuse should be carried out as per the laboratories' protocols and confirmation of each positive result. Obtaining suitable samples of suitable volume is therefore critical, and in some cases, sufficient blood may not be available for complete testing and therefore analyses need to be prioritized. The medical history of the victim is therefore important, for example, if they are prescribed a benzodiazepine. It may not be necessary to carry out a benzodiazepine confirmation analysis unless there is a potential for this to contribute to the impairment of another drug, for example, alcohol.

With the increase in sensitivity and selectivity of analytical instrumentation, laboratories are becoming increasingly able to detect drugs and their metabolites for longer periods of time. The usefulness of the toxicological component of DFC investigation is therefore extending in time with drug metabolites being detected more than 10 days post incident. This information should be made public so that victims of these crimes realize that it may still be useful to report, and the investigators can encourage victims to provide samples for

longer time frames than the 24–48 h currently utilized in many jurisdictions.

Interpretation of Toxicological Results in DFC

Of final note is the importance of correct interpretation of data obtained. Reporting toxicologists must have an awareness of the pharmacology of the drugs involved and remember that absence of evidence does not always equate to lack of a crime. By understanding how long a drug is present in a sample along with the limitation of the instrumentation available, a fair interpretation of the data should be possible.

Regarding hair analysis, the limitations regarding precision of timeframe, issues regarding washout, etc. should be acknowledged.

However, the toxicologist should also remember they cannot prove who administered the drug and the exact time that it was administered. It is possible that an alleged victim could have taken a sedating drug in order to fool the system and wrongly incriminate someone or in order to calm their nerves following an actual offense. The toxicologist can only report the results they have found and provide an interpretation based on the facts available to them at the time of reporting.

Conclusion

Drug-facilitated crimes need to be investigated in terms of both the reported crime, for example, sexual assault and the toxicological evidence. Owing to the sedating and amnesic properties of many of the drugs found in these crimes, they can be late-reporting cases, and thus, an understanding of the properties of the drugs and the limitations of analytical instrumentation are important considerations. Worldwide studies indicate that the most prevalent drug in cases of this type is alcohol and that a wide range of sedative drugs can be used and are found in toxicological samples. The use of hair in these cases is becoming of increased importance and therefore this matrix should be collected where possible.

Introduction

The road transport system is one of the most hazardous and most expensive in terms of human lives lost in the world. The consumption of psychoactive substances such as alcohol, drugs, and certain medicines is likely to endanger the driver's ability to drive safely. Impaired driving is still one of the major causes for road accidents or road deaths in Europe and elsewhere in the world. Driving is a complex task, requiring the cooperation of several different cognitive and psychomotor functions at once. Crashes can be the consequence of many different factors, which can be classified into three categories: the road, the vehicle, and the driver. A crash is rarely attributable to only one factor; therefore, it is very difficult to precisely determine the contribution of alcohol and/or drugs in a collision.

Influence of Drugs on Performance

Research on the effects of drugs on performance can be broadly separated into experimental and epidemiological studies. In experimental research, different doses of a certain drug are administered to volunteers, and the effects on performance are measured and compared to those of a placebo and on a positive control. Epidemiological studies give information concerning the effects associated with the use of drugs by examining the incidence of drugs in various populations.

The possible effects of several drug classes are described (see [Table 1](#)). The reader should keep in mind that the effect and the duration depend on many factors such as the dose, the route of administration, and the individual characteristics and susceptibility of the user.

Alcohol

Alcohol is a central nervous system depressant. Many studies have already been performed to determine the effects of acute alcohol ingestion on cognitive functions and driving performance. These studies found that numerous driving-related skills are degraded beginning at low blood alcohol concentrations (BACs). With increasing BAC, reaction time is increased and coordination is decreased. The main effects of alcohol on

the driving skills are slowed reaction time, poor judgment, impaired vision and hearing, poor coordination, and a false sense of confidence. Its toxic effects vary considerably from person to person and are influenced by variables such as gender, body weight, rate of consumption (time), and total amount consumed. When a certain tolerance has developed, despite feeling unaffected by alcohol, a person may be over the 0.5 g l^{-1} limit and have slowed reactions, resulting in impaired driving skills.

Cannabis

Cannabis has both hallucinogenic and central nervous system-depressant properties. Cannabis acutely reduces some cognitive and psychomotor skills, such as equilibrium, coordination, tracking ability, perception, motor impulsivity, and vigilance, and slows reaction time. These effects are mostly dose dependent. Cannabis can also have an effect on behavior. The results of experiments in laboratory settings are contradictory, while in some driving studies (with rather low doses) users are aware of the impairment and often compensate their driving style by driving more slowly, overtaking less, or keeping longer distances from other vehicles. Nevertheless, the driver is still unable to completely compensate for the loss of capability in some psychomotor skills. When combined with alcohol, the effects appear to be considerably greater than would be expected. Other studies have found that tetrahydrocannabinol (THC) consumption significantly impairs the subjects' performance in driving tests at whatever dose used. Some research suggested that perceptual motor speed and accuracy, two very important parameters of driving ability, seem to be impaired only immediately after cannabis consumption, while other studies found data suggesting a more lasting toxic effect on the central nervous system, which persists even after all drug residues have left the system.

Stimulants (Amphetamine, Methamphetamine, and Cocaine)

Stimulants produce a number of effects on drivers, which range from the acute phase (shortly after drug consumption) to the postacute phase, when drug withdrawal or abstinence can be an issue. Stimulants cause a strong central stimulation and euphoria. The user thinks he can do everything and will take

Table 1 Influence of drugs on performance.

	<i>Side effect</i>		
	<i>Acute</i>	<i>Chronic</i>	<i>Combination</i>
Alcohol	Slowed reaction time, poor judgment, impaired vision and hearing, poor coordination and a false sense of confidence, risk-taking behavior	Slowed reflexes, slower information processing, significant loss of cognitive functions. When drinking regularly, one will be able to drink larger quantities before feeling or appearing intoxicated (tolerance)	The sedative effects of both alcohol and sedative medications can enhance each other. Various combinations definitely impair the driving performances
Cannabis	Mydriasis, dry mouth, anxiety, decrements in cognitive and psychomotor functions, impairment of the road tracking ability (accuracy to steer a car), hazard perception, increase in lateral position variability	Defects in cognitive functions and psychomotor functions, amotivational behavior	Additive or even synergistic relation with negative effects of alcohol. In combination with cocaine: additional impairment compared to the use of cannabis or cocaine alone Cannabis tends to increase the intensity of the performance impairment produced by alcohol
Stimulants	Lack of coordination, sensory disturbances, disorientation, restlessness, lapses of attention, fatigue, difficulty reacting appropriately to safely control a vehicle, increased risk taking, overconfidence in driving skills, drowsiness, or rebound fatigue (as the effects wear off). Positive effects and negative effects on cognition and psychomotor performance	Defects in cognitive functions, increased impulsivity, and depression	Alcohol reinforces negative effects and can cause some additional defects. Some effects of alcohol can be diminished
Narcotic analgesics	Miosis, analgesia, psychomotor and cognitive decrements, euphoria ('rush'), impaired judgment coordination, visual disturbances or dizziness, blurred vision, impaired visual fields and nighttime vision, drowsy driving	Cognitive and psychomotor decrements, depression, anxiety	Combination of narcotic analgesics and other CNS depressants (including alcohol) has additive depressant effects
Central nervous system depressants	Impairment of mental and motor functions, drowsiness and light-headedness, sedation, and anticholinergic effects. The level of impairment varies from person to person and between different medications within the same therapeutic class.	Withdrawal symptoms, adverse effects on mood and cognitive functions	Alcohol can have an additive effect on sedation and psychomotor impairment
GHB	Signs of impairment are consistent with those of a CNS depressant, including erratic driving (weaving, swerving, ignoring road signs), confusion, slowed reaction time, increased risk taking, unresponsiveness, tunnel vision, lack of balance, unsteady coordination and varying states of wakefulness	The long-term effects of GHB use are unclear. As the effects of GHB are similar to those of sedative drugs, it is possible for the user to become physically and psychologically dependent	The adverse effects of GHB may be greatly increased by the use of alcohol. Alcohol is particularly dangerous in combination with GHB, as it can be difficult to control the dose

more risks, but after some time (hours or days depending on the pattern of use), the subject is exhausted and falls asleep (crash phase). Tests in driving simulators revealed that the intake of amphetamine causes an overall decrease in the accuracy of simulated driving by inducing problems such as incorrect signaling, failing to stop at a red traffic light, and slow reaction times. During the crash phase following the use of amphetamines, the subject feels very tired, unable to combat sleep, and depressed. This phase can last for several days. The

desired effects of cocaine are similar to those of the amphetamines, but the onset is slower and the duration is longer. The use of a combination of alcohol and cocaine decreases psychomotor impairment and improves performance on cognitive tests when compared to the use of alcohol alone. However, cocaine also decreases the subjective feeling of drunkenness caused by alcohol and can reinforce detrimental effects of other drugs such as cannabis. The combination of cannabis and cocaine causes additional impairment to the use of cannabis or cocaine alone.

Conversely, alcohol can reinforce the negative effects of the stimulants and can cause some additional defects.

Narcotic Analgesics

The narcotic analgesics include the drugs heroin, methadone, and morphine. Narcotic analgesics are used in medicine as strong analgesics, for relief of severe or chronic pain. Some, for example, methadone, are also used to treat addiction to opioids. When these substances are used occasionally under the guidance of a physician, they can be a safe and effective pain reliever. Regular use of narcotic drugs can be addictive, causing withdrawal symptoms. The user of narcotic analgesics generally feels intense euphoria ('rush') accompanied by a warm flushing of the skin, dry mouth, and heavy extremities, and alternates between a wakeful and drowsy state. Tolerance to the effects of opioids is well documented, and there is some evidence that people who become stabilized on moderate doses of opioids have tolerance to some of the impairing effects of the drugs.

Central Nervous System Depressants

This category includes drugs such as benzodiazepines (e.g., diazepam and temazepam), sedative hypnotics (e.g., zolpidem and zopiclone), some antidepressants, muscle relaxants, and some antihistamines. These substances have a legitimate therapeutic use. Discussing the potential effect of these substances on the driving abilities becomes difficult because sometimes, in some individual cases, poor compliance of the above-mentioned therapeutic substances can lead to even more dangerous situations on the road than when the substance/medicine is used properly. For example, some studies showed that a depressed driver, treated with an impairing drug such as an antidepressant, is a better driver than an untreated driver.

Benzodiazepines are used primarily for rapid relief of anxiety, muscle relaxation, sedation, and hypnosis (sleeping aid), and for their anticonvulsant effects. The most frequently encountered adverse effects are impairment of mental and motor functions, drowsiness, and light-headedness. Benzodiazepines cause impairment ranging from mild to substantial depending on the half-life of the drug and their use. Studies have shown that short-acting benzodiazepines without active metabolites are less impairing than long-acting benzodiazepines since the effects do not persist much longer than several hours. When combined with other substances, especially alcohol, the risk of being involved in a (serious or fatal) collision is increased. It should be noted that with regular use, tolerance develops reducing the degree of impairment.

Antihistamines are drugs used to treat allergic reactions. Depending on the distribution of the drug in the body, the adverse effects can include sedation, digestive tract troubles, and anticholinergic effects. The antihistamines are divided into first-generation and second-generation histamines. The second-generation drugs are generally nonsedating, although exceptions exist. Alcohol can have an additive effect on sedation and psychomotor impairment, particularly when combined with more sedating first-generation drugs such as diphenhydramine, doxylamine, and the pheniramines.

Antidepressants are substances commonly prescribed for mood disorders, anxiety, and sometimes pain. There are first- and second-generation antidepressants and an atypical group. The second-generation drugs, SSRIs (selective serotonin reuptake inhibitors) or SNRI (selective serotonin–norepinephrine reuptake inhibitor), are associated with fewer adverse effects compared to the first generation ones, mainly because of greater selectivity. Adverse effects encountered with first-generation antidepressants are anticholinergic effects (blurred vision) and sedation, while second-generation antidepressants seem not to cause major impairment of cognition or psychomotor skills. Consequently, SSRIs and SNRIs are generally regarded as behaviorally safe drugs, whereas first-generation antidepressants are classified as impairing, particularly because of their sedative effects.

New Psychoactive Designer Drugs

The popularity of this group of relatively new drugs, such as mephedrone, piperazines, gamma-butyrolactone (GBL) or gamma-hydroxybutyrate (GHB), and synthetic cannabinoids, has increased over the past years. Except for those on GHB, very few data are available to establish the prevalence of these new drugs as well as to consider the effect of these drugs on driving or road safety in general. From what is known of the chemical structures of the drugs, the effects of these new drugs on road safety may be inferred by reference to research on similar drugs.

Chronic Effect of Drugs

Chronic use refers to regular (often daily) use over some days to weeks. The effects of drugs on performance can not only be the consequence of the acute effects of the drugs (including the 'crash' phase after drug use) but also of the impairment caused by withdrawal or by chronic use.

The effects of cannabis usually last for some hours, but in high users, they can last for up to 24 h, indicating that a person using cannabis in the evening can still experience residual impairment the following day. Chronic use of cannabis also affects driving performance, even when intoxication is no longer present. Very heavy chronic use of marijuana is associated with persistent decrements in neurocognitive performance even after 28 days of abstinence.

The chronic use of amphetamines causes depression and has obvious negative effects on cognitive and psychomotor skills, which last longer than the period of intoxication and are often correlated to the severity of use. It is also linked to psychiatric problems, such as depression, hallucinations, schizophrenia, and paranoia. The use of MDMA (ecstasy) can cause a decrease in attention, short-term and long-term memory, verbal memory, visuospatial skills, executive functioning, and prediction of object movement under divided attention. Chronic ecstasy use can lead to higher impulsivity.

Chronic use of cocaine can lead to significant cognitive deficits, such as impaired psychomotor performance, impulsive behavior, and even psychosis.

Finally, the withdrawal symptoms of certain medicines (e.g., venlafaxine and paroxetine (antidepressants)) can cause serious impairment due to adverse effects on mood and cognitive functions.

Epidemiology and Crash Risk

Prevalence of Drugs in the General Driving Population or in a Subset of Drivers

The prevalence of drugs in the general driving population can be estimated by means of roadside surveys, in which samples of randomly stopped drivers are analyzed. About 1–6% of drivers stopped during roadside surveys in Europe tested positive for drugs in oral fluid (OF). Large differences in prevalence between countries exist. Despite differences in methodology in studies, cannabis is the most frequently detected drug followed by benzodiazepines. The combination of alcohol and drugs is found in about 0.3–1.3% of the general driving population. The latest National Roadside Survey of Alcohol and Drug use conducted in 2007 in the United States found a prevalence of 16% drug-positive at night when either OF or blood tests were used.

Studies have shown that drugs are found in 19–50% of drivers injured in a traffic crash, 6–35% of drivers killed in a traffic crash, and 55–99% of drivers suspected of driving under the influence of drugs (DUID). These figures vary widely due to regional differences and variations in methodology. For example, in some studies, blood was analyzed, while others used urine or OF. The variation in detection times in these matrices can influence the results. Furthermore, there are differences in the types of drugs analyzed and the kind (and sensitivity) of analysis method used. A large-scale epidemiological study called DRUID (driving under the influence of alcohol, drug, and medicines) recently analyzed the prevalence of alcohol and other psychoactive substances in seriously injured drivers in six different European countries with a standardized study design. Alcohol ($\geq 0.1 \text{ g l}^{-1}$) was the most common finding, with a range between 18% (Lithuania) and 42% (Belgium), followed by THC (range 0.5% – Lithuania and 7.6% – Belgium) and benzodiazepines (0% – The Netherlands and 10% – Finland). Again, the most prevalent drug found was cannabis. Other important drugs were amphetamines, benzodiazepines, and opiates.

Risks Associated with DUID

Crash risk can be determined by comparing the prevalence of a certain drug in the general driving population to the prevalence in drivers who were involved in a traffic crash. Several studies have already shown that an increasing BAC is associated with increasing crash risk. Other studies have calculated the crash risk associated with other psychoactive substances. The impaired motorists, methods of roadside testing, and assessment for licensing study in the Netherlands revealed that drivers under the influence of benzodiazepines alone have a relatively higher risk for an accident, which is three times greater than the risk of a drug-free driver. The highest risk was associated with the use of drugs in combination with alcohol ($\geq 0.8 \text{ g l}^{-1}$), namely, a 179 times higher risk! A study in Canada, for example, showed that the crash risk associated with driving under the influence of cocaine, benzodiazepines, and cannabis is, respectively, 5, 2.5, and 2.2 times higher than that of a person who has not consumed these drugs.

Some studies have estimated the risk of being responsible for a traffic crash while DUID. The results indicate that

increasing BACs are associated with increasing crash risk. They also show that driving under the influence of cannabis increases the risk of being responsible for a crash. The risk increases with increasing cannabis concentration in blood, indicating a causal relationship between cannabis and crashes. In a French study on cannabis intoxication and fatal road crashes, cannabis detection was associated with increased risk of responsibility (odds ratio = 3.32, 95% confidence interval 2.63–4.18). The risk of being responsible for a fatal accident when driving under the influence of cannabis and alcohol is approximately equal to the multiplication of the risks when driving under the influence of cannabis or alcohol alone. Responsibility analyses have also shown that benzodiazepines and cocaine are associated with increased risks of being responsible for an accident and that the risk is higher for a combination of alcohol and benzodiazepines than that for benzodiazepines alone.

The association between the use of benzodiazepines and the risk of road traffic crashes has now been documented with consistent results in several studies, but the effect of other medicines has been less assessed and the results of available studies are often inconsistent. A recent French study investigated the association between prescription medicines and the risk of road traffic crashes and estimated the attributable fraction. Medicines were grouped according to the four risk levels of the French classification system (from 0 (no risk) to 3 (high risk)). The study showed that users of level 2 (odds ratio = 1.31) and level 3 (odds ratio = 1.25) prescription medicines were at higher risk of being responsible for a crash. The fraction of road traffic crashes attributable to level 2 and 3 medicines was 3.3% (2.7–3.9%).

Legislation

Each developed country has its specific legislation to deal with DUID. There is a lack of uniformity in the way in which nations approach the drugged driving problem. Generally, there are two major types of DUID legislation, namely, 'impairment' legislation and 'per se' legislation.

Impairment Legislation

In impairment legislation, the prosecution must demonstrate that the driver was impaired, not fit to drive, or 'under the influence.' The analysis of drugs in body fluids only provides corroborating evidence as to the cause of the impairment. This kind of legislation is subjective and requires the assessment by a medical doctor or a specially trained police officer. As a consequence, many of the countries with this kind of legislation experience difficulties in obtaining convictions. For this reason, and in analogy with alcohol, many countries have introduced 'per se' laws. Examples of countries with 'impairment' legislation are Norway and the United Kingdom.

'Per se' Legislation

A 'per se' law prohibits driving if drugs are present in blood, serum, plasma, or OF above a certain threshold. Since the prosecution does not have to prove that the driver was

impaired, this kind of legislation facilitates the enforcement process. The threshold concentrations, or cutoffs, used are analytical detection limits, meaning that any detectable concentration of a drug constitutes an offense. Therefore, these laws are sometimes called *zero-tolerance* laws. Presently, Germany, Belgium, Sweden, France, Finland, Luxembourg, Switzerland, Denmark, a number of Australian states, and 17 states of the United States have introduced 'per se' legislation in addition to the 'impairment' legislation. The analytical cutoffs in some European countries are given in [Table 2](#).

There is no consensus on the analytical cutoffs between the different countries. This lack of consensus can be partially attributed to the use of different biological matrices (serum in Germany, plasma in Belgium, and whole blood in Australia, France, Sweden, and Switzerland) and the different consequences of a positive result: for example, in Belgium there is a criminal sanction, while in Germany there is an administrative sanction. The main challenge in establishing legal regulations combating drugged driving is to define clear rules for detecting and sanctioning an impaired driver. New (analytical) technologies are increasingly more sensitive and can detect very small quantities of substances. Positive results in per se laws do not necessarily prove impairment due to their presence, that is, when an illicit or medicinal drug was consumed many hours before and psychoactive effects are no longer present.

Two-Tier System

Per se limits are combined with an impairment approach. This system combines the advantages of the two legal regulations. For a limited list of drugs, the per se approach allows easy prosecution, and the impairment legislation is used to cover less frequently used drugs and other special cases like drug combinations and the effects of drug withdrawal.

Detection of Drugs in Drivers

Checklists for Impaired Driving

In many countries, checklists have been developed to standardize reporting of clinical signs of recent drug

consumption, which are used by police officers (or physicians) to document that the driver is fit or not fit to drive. In the United States, the drug recognition evaluator (DRE) is a police officer trained to recognize impairment in drivers under the influence of drugs other than, or in addition to, alcohol. The Los Angeles Police Department originated the program in the early 1970s. DRE conducts a detailed, diagnostic examination of persons arrested or suspected of drug-impaired driving or similar offenses using a 12-step protocol. On the basis of the results of the evaluation, the DRE forms an expert opinion on the following: (1) is the person impaired and, if so, is the person able to operate a vehicle safely? (2) Is the impairment due to an injury, illness, or other medical complication, or is it drug related? (3) Which category or combination of categories of drugs is the most likely source of the impairment? An example of a checklist is given in [Figure 1](#).

Roadside Detection

For many years, police officers involved in road safety have expressed the need for a rapid and reliable roadside screening test for drugs, similar to an alcohol breathalyzer. This would help determine which drivers have to provide a blood sample or it would help take immediate administrative measures like confiscating the driver's license or impounding the vehicle. As illegal drugs are not released in measurable amounts in the breath, roadside drug testing must be based on other specimens. The use of OF as an alternative matrix for the detection of drugs of abuse has increased steadily over the last decade. Roadside OF testing to detect drug driving has already been introduced in the legislation of Belgium, France, Spain, and several Australian states.

The experience of the police has shown that performing on-site urine screening at the roadside is very complicated, often potentially intrusive or vulnerable to adulteration. In addition, a positive urine test may indicate exposure to a drug several days previously for long half-life drugs. Detection of drugs in OF indicates more recent drug use, and there is some correlation with impairment. On-site screening for drugs of abuse in OF provides a relatively quick and increasingly effective means of detecting if a motorist has consumed drugs or medicines.

CHECKLIST DETECTION ILLEGAL DRUGS

Survey session No. ..., Day, Date, Time span.....
 Police observer: (police team)

Subject No.

1. Subject gender: ☐ male ☐ female

2. Signs of impairment

Observation at some distance when subject enters and leaves mobile research unit:

- ☐ unsteady on one's feet, swaggering (opiates)
- ☐ uncoordinated movements (opiates)
- ☐ drowsy, sleepy (opiates)
- ☐ euphoria (opiates, XTC, amphetamine, cocaine)
- ☐ not understanding instructions (opiates)
- ☐ incoherent speech (opiates)
- ☐ chattering (XTC, amphetamine, cocaine)
- ☐ slurred speech (THC)
- ☐ low, rasping voice (opiates)
- ☐ scratching one's face (opiates)
- ☐ trembling (XTC, amphetamine, cocaine)
- ☐ shaking leg (XTC, amphetamine, cocaine)
- ☐ excited, aggressive behaviour (amphetamine, cocaine)

Observation at close range before and during breath test for alcohol:

- ☐ bloodshot eyes (THC, XTC, amphetamine, cocaine)
- ☐ red nostrils (cocaine)
- ☐ trembling eyelids (XTC, amphetamine, cocaine)
- ☐ sniffing (cocaine)
- ☐ undue perspiring (opiates)
- ☐ swallowing (THC, opiates, XTC, amphetamine, cocaine)
- ☐ smell of hash (THC)
- ☐ pinpoint pupils: <3.0 mm (opiates)
- ☐ dilated pupils: >6.5 mm (XTC, amphetamine, cocaine, sometimes THC)

3. Breath test for alcohol; result (BAC) g/l (in two decimals)

4. Question (while waiting for breath test result):

Did you during the past 24 hours use hash, weed or other illegal drugs?

☐ no

☐ yes, namely:.....

Name of medicine, if used:.....(checklist
benzos!)

5. Test pupil reaction to light (only if pupils are dilated and BAC is below 0.2 g/l):

☐ normal reaction

☐ slowed reaction (XTC, amphetamine, cocaine, THC)

6. Police officer's final judgement about the use of impairing drugs other than alcohol

☐ did not use

☐ did use; substance:

☐ in doubt between use or not, because:.....

SEE OVERLEAF FOR SOME IMPORTANT REMARKS

Figure 1 An example of a checklist to detect illegal drug use.

Nevertheless, a positive OF on-site screening result can only be interpreted as past use or exposure to drugs; it does not indicate impairment.

In the Rosita-2 study (performed between 2003 and 2005), the analytical evaluation of the cannabis tests showed a sensitivity and specificity in the range of 0–74% and 70–100%, respectively. In the DRUID project, eight on-site tests were evaluated but none of the devices performed well (above 80% for sensitivity, specificity, and accuracy) (Figure 2). Sensitivity and specificity in the range of 23–81% and 88–100%, respectively, for the different drug classes were found.

Despite the rather low sensitivity of the drug-testing devices, the experience in the state of Victoria in Australia shows that random roadside testing of OF of drivers for methamphetamine, ecstasy, and cannabis has a deterrent effect. The percentage of positive drug tests have decreased over the years 2005–09 (from 2.6% in 2005 to 0.9% in 2009). Also, the prevalence of drugs found in killed drivers slightly decreased (2005: 40%; 2009: about 32%), but the target drugs decreased more rapidly (24% in 2005 to 16% in 2006).

It is possible that future developments could lead to on-site screening of capillary blood obtained by a finger prick and

Figure 2 Some examples of on-site drug-testing devices; from the upper left corner and going clockwise: Mavand Rapid STAT, Innovacon OrAlert, Varian OraLab, Cozart DDS 806, and DrugWipe 6S.

confirmation of the presence/absence of drugs by the analysis of dried blood spots. Possible advantages of this approach would be the easy transportation (no need for refrigeration or shipping on dry ice), the stability of parent substances at ambient temperature, and less risk of loss of sample (e.g., breakage of glass tube of blood) or of infection.

Evidentiary Analysis

Blood is considered to be the best matrix for confirmation analysis because the presence of drugs in blood corresponds best to recent use and impairment. In many countries with per se legislation, the only legally allowed evidence for DUID is confirmation of the presence of drugs in blood. The most widely used method is gas chromatography–mass spectrometry (GC-MS) because of its sensitivity and specificity. However, the procedure is labor intensive and time-consuming, as extraction and derivatization are necessary for sample preparation. Therefore, liquid chromatography–(tandem) mass spectrometry (LC-MS/MS) procedures have been introduced for different classes of drugs for confirmatory analyses or even for screening and confirmation in one step. Several laboratories have developed methods that detect a large series of different drugs in one step in a small sample volume.

In Germany, Italy, and other countries, hair analysis is used for (re)granting license to drug-dependent persons. The hair samples are first screened by immunoassay and positives are confirmed by chromatographic techniques. The major practical advantage of hair testing is its longer detection window, which is weeks to months, depending on the length of hair shaft analyzed (hair grows at a rate of approximately 1 cm per month). Hair analysis can also be used for monitoring alcohol abstinence, by quantitating different markers like ethyl glucuronide and/or fatty acid ethyl esters. Other advantages of hair are its stability and ease of transportation.

Conclusion

There is an increasing knowledge regarding the influence of drugs on performance and the prevalence of drugs other than

alcohol in road traffic. Experimental and epidemiological studies clearly show that many drugs can have a detrimental effect on driving performance. These negative effects are more pronounced when drugs are combined with alcohol. DUID is associated with increased crash risks and increased risk of being responsible for a traffic crash. These risks increase even more when drugs are taken in combination with alcohol compared to when drugs are taken alone.

There is a clear move toward ‘per se’ legislation, although some countries at this time have decided to stay with impairment legislation. The detection of drivers under the influence of drugs can be done by the police by means of screening tests. The interest in OF screening tests has grown significantly. Studies however have shown that the currently available on-site devices lack sensitivity, but they are steadily improving. More recent methods developed for confirmation analysis use LC-MS/MS.

Glossary

Anabolic steroids Steroids with anabolic properties.

Beta-adrenoceptor agonists Agonists of the beta-adrenergic receptors.

Corticoids Gluco- and mineralo- corticoids.

ELISA Enzyme immunoassay.

GC-MS Gas chromatography coupled to mass spectrometry.

MS Mass spectrometry.

RIA Radioimmunoassay.

Tandem MS Triple quadrupole mass spectrometry.

Introduction

Using hair as a medium to analyze drug exposure has received increased attention in recent times because of the less embarrassing circumstances of collection, its long drug detection window, and because it does not decompose like other body tissues after death.

In 1979, Baumgartner and colleagues published the pioneering report on using radioimmunoassay to detect morphine in the hair of heroin abusers. Today, chromatographic procedures, especially those coupled with mass spectrometry (MS) or tandem MS, represent the gold standard for the identification and quantification of drugs in hair, owing to their higher sensitivity and specificity.

Hair analysis is now routinely used as a tool for detection of xenobiotics (drugs of abuse, pharmaceuticals, environmental contaminants, doping agents, etc.) in forensic science, traffic medicine, occupational medicine, and clinical toxicology.

This article summarizes and discusses some applications and methods used in hair analysis.

Biology of Hair

Hair is a product of differentiated organs in the skin of mammals composed of protein (65–95%, keratin essentially), water (15–35%), lipids (1–9%), and minerals (<1%). The hair shaft consists of an outer cuticle that surrounds a cortex. In some types of hair, a central medulla surrounds the cortex. The hair shaft develops in a follicle closely associated with the sebaceous and apocrine glands. The growth of hair occurs in cycles, alternating between periods of growth (*anagen* phase) and periods of quiescence (*catagen* and *telogen* phases). About the 1 million hair follicles of the adult scalp, comprising approximately 85% of the hair, are in the growing phase and the remaining 15% is in a quiescent stage. Hair is produced during 4–8 years for head hair (<6 months for nonhead hair) at a rate of approximately $0.22\text{--}0.52\text{ mm day}^{-1}$ or $0.6\text{--}1.42\text{ cm month}^{-1}$ for head hair. The growth rate depends on type of hair, physiological factors, and the anatomical location.

The exact mechanism by which chemicals are bound in hair is not known, but it is generally considered that xenobiotics can enter hair by at least three mechanisms: from the blood during formation of hair in the follicle, from transfer of

substances in sweat and sebum, and from the external environment.

Hair is best collected from the area at the back of the head, called the *vertex posterior*. Compared with other areas of the head, this area has less variability in the hair growth rate, the number of hairs in the growing phase is more constant, and the hair is less subject to age- and sex-related influences. Pubic hair, arm hair, and axillary hair are possible alternative sources for drug detection when scalp hair is not available; however, interpretation is more complex.

Hair Analysis

The most crucial issue facing hair analysis is the avoidance of false-positive results caused by passive exposure to the drug. In most laboratories, hair analysis starts with a wash step to remove external contamination.

Hair analysis involves at least five steps:

1. decontamination of the hair;
2. preparation of the hair: pulverization, segmentation into short segments;
3. incubation: in methanol, acid, sodium hydroxide, buffer
4. extraction: liquid/liquid, solid phase, solid phase micro-extraction; and
5. analysis: enzyme-linked immunosorbent assay (ELISA) and/or chromatography (gas, liquid) coupled to mass spectrometry (tandem MS).

Cutoff concentrations from the Society of Hair Testing (SoHT) and expected concentrations in hair for drugs of abuse are presented in Table 1.

These cutoffs were established to avoid false-positive results due to external contamination. They are used both for ELISA screening and chromatographic confirmations in workplace drug testing. In most cases, they are not applied in forensic cases, where sometimes a single exposure has to be demonstrated.

ELISA technique, daily used by numerous laboratories to screen xenobiotics in hair, requires hair decontamination, followed by a thin grinding of the specimen and its incubation in methanol. After evaporation of the solvent, appropriate buffer is added to the dry extract and ELISA is performed following the procedures (same as for blood and urine) of the manufacturers.

Table 1 SoHT cutoff concentrations (when tested by GC/MS) and expected concentrations for drugs of abuse in hair

Drug	GC/MS cutoff concentration	Expected concentrations
Heroin	0.2 ng mg ⁻¹ of 6-acetylmorphine, morphine	0.5–100 ng mg ⁻¹ , in most cases <15 ng mg ⁻¹
Cocaine	0.5 ng mg ⁻¹ of cocaine and 0.05 ng mg ⁻¹ of benzoylecgonine and cocaethylene	0.5–100 ng mg ⁻¹ , in most cases <50 ng mg ⁻¹ , in crack abusers >300 ng mg ⁻¹ is possible
Amphetamine, MDMA	0.2 ng mg ⁻¹ for each drug	0.5–50.0 ng mg ⁻¹
Cannabis	0.1 ng mg ⁻¹ for THC 0.2 pg mg ⁻¹ for THC-COOH	THC: 0.05–10 ng mg ⁻¹ , in most cases <2 ng mg ⁻¹ THC-COOH: 0.5–50 pg mg ⁻¹ , in most cases <5 pg mg ⁻¹

MDMA, 3,4-Methylenedioxymethamphetamine; THC, Δ^9 -tetrahydrocannabinol; THC-COOH, Tetrahydrocannabinol-11-oic-acid.

Table 2 Main characteristics and performance of analyses in urine and hair

	Urine	Hair
Drugs of abuse and pharmaceuticals detected ^a	All	All
Main compounds	Metabolites	Parent drugs and metabolites
Detection time window	2–3 days	Months, years
Analytical techniques	Immunoassays, followed by chromatography/mass spectrometry	Immunoassays, followed by chromatography/mass spectrometry
Specificity	Pharmacological group identification, then specific confirmation	Pharmacological group identification, then specific confirmation
Analysis duration	+	+++
Type of measurement	Incremental	Cumulative
Sample collection	± Invasive	Noninvasive
Adulteration	Possible	Unlikely ^b
Preservation	–20°C	Ambient temperature

^aOnly doping hormones (erythropoietin, growth hormone, etc.) are not incorporated in hair.

^bCosmetic treatment will reduce concentrations.

Applications

Verification of History of Drug Use

By providing information on exposure to drugs over time, hair analysis may be useful in verifying self-reported histories of drug use in any situation in which a history of past rather than recent drug use is desired. During controlled studies, a drug user is not able to hide their drug abuse as the window of detection is often so long, that is, months. Urine or blood tests are not useful to detect drug use when drugs are consumed every few days even when the tests are repeated.

The advantages and disadvantages of drug detection in urine and hair are presented in Table 2.

Hair analysis can also provide a retrospective calendar of an individual's drug use. For this, multisectional analysis is required and involves taking a length of hair and cutting it into sections to measure drug use during shorter periods of time. The hair must be cut as close as possible to the scalp and particular care is also required to ensure that the individual hairs in the cutoff tuft retain their original orientation.

The most extensive study on sectional analysis for drugs of abuse has involved patients in rehabilitation centers. Segmental hair analysis is used to verify both their previous drug history and their recent enforced abstinence. To verify abstinence, the lowest drug concentration is found in the segments nearest the root.

The differentiation of heroin users from individuals exposed to other sources of morphine-based alkaloids can be

achieved by identifying directly heroin or its metabolite, 6-acetylmorphine.

Hair analysis is suitable for accurately monitoring relative changes in drug intake in the same individual. In several studies (although there is a lot of variability from one person to another), it has been shown that a doubling of drug dose in the same individual results in an approximate doubling of the drug content in the hair, which is not always the case for blood and urine drug level. Patients who received constant methadone doses under close supervision should show some constancy in their methadone levels in hair.

Several studies have suggested that the hair color (or the melanin content) may be the major determinant of drug binding and, consequently, may result in color bias in hair testing. Researchers have demonstrated that different hair types incorporate differing amounts of drugs when exposed under identical conditions. The higher accumulation of alkaline substances (such as cocaine or heroin) in black hair when compared with blond hair will need to be addressed (or controlled) in order not to discriminate specific ethnic groups due to hair color.

Alcohol Abuse

Considering the large scale of alcohol-associated problems, the diagnosis of excessive alcohol consumption is an important task from a medical and legal point of view. Major markers of ethanol consumption in hair are ethyl glucuronide (EtG) and

fatty acid ethyl esters (FAEE). Detection of EtG in hair is associated with excessive alcohol consumption, whereas a negative result does not unambiguously exclude the alcohol abuse. Investigations on the FAEE can also be used to monitor excessive alcohol consumption. FAEE are formed in the presence of ethanol and free fatty acids, triglycerides, lipoproteins, or phospholipids by an FAEE synthase found in liver and also in hair roots. FAEE determination is of interest as they appear responsive to alcohol-induced organ damage. Four FAEE (ethyl myristate, ethyl palmitate, ethyl oleate, and ethyl stearate) are the most suitable markers for the detection of heavy alcohol consumption and show differential concentrations in hair of children, adult teetotalers, and social drinkers in comparison with FAEE concentrations found in hair of alcoholics.

The SoHT provides guidelines for hair testing for chronic excessive alcohol consumption. The cutoff for EtG in hair to strongly suggest chronic excessive alcohol consumption is proposed at 30 pg mg^{-1} scalp hair measured in the 0–3 up to 0–6 cm proximal segment. The cutoff for the sum of the four FAEE esters in hair to strongly suggest chronic excessive alcohol consumption is proposed at 0.5 ng mg^{-1} scalp hair measured in the 0–3 cm proximal segment. If the proximal 0–6 cm segment is used, the proposed cutoff is 1.0 ng mg^{-1} scalp hair. In both cases, if samples less than 3 cm are used, the results should be interpreted with caution. At this time, there is no consensus on how to determine abstinence.

Verification of Doping Practices

Athletes use both endogenous and exogenous anabolic steroids as they increase lean body mass and strength, as well as aggressiveness, and result in shorter recovery time between workouts.

The greatest use of hair in this context is investigating false negatives results in negative test results on blood or urine, particularly if banned substances have been used more than a few days before the competition. Hair can also indicate the history and frequency of drug intake as repetitive use can be demonstrated by segmental analysis along the hair shaft.

Unlike testosterone in urine, the interpretation of concentrations in hair can be difficult. The range between physiological concentrations of testosterone and those found in abusers is small. Therefore, to complement testosterone determination, the identification of unique testosterone esters in hair enables an unambiguous determination of doping because the esters are exogenous substances and therefore could not come from endogenous testosterone.

Another advantage of hair analysis is the possible discrimination between nandrolone and abuse of other 19-norsteroids (norandrostenedione and norandrostenediol), which lead to the same urinary metabolites (norandrosterone and noretiocholanolone). This is obviously not possible in urine as hair can identify the identity of the parent compounds.

In case of longitudinal surveys of athletes, hair analysis appears as the solution of choice to document doping practices.

Beta-adrenoceptor agonists are banned in competition sports because of their sympathomimetic properties (stimulant effects) and their activity as anabolic agents at higher dosages. However, salbutamol is permitted to be used by inhalers only

and must be declared prior to the competition. As the drug is permitted for specific therapeutic purposes, together with a medical prescription, it is relatively easy to evade a positive urine test (by having a urine concentration below the positive cutoff, such as for salbutamol or corticoids). Again, segmental hair analysis would document unambiguously doping by the athletes, when the drug (such as a corticoid or an anabolic compound) is found in several consecutive hair sections. This can also be controlled in case of long-term abuse of corticoids.

Regranting of Driving Licenses

The major practical advantage of hair testing compared with urine and blood testing for drugs is its larger detection window, which is weeks to months depending on the length of the analyzed hair shaft, against a few days for urine for most drugs. There is a reasonable agreement that the qualitative results obtained from hair analysis are valid provided that contamination cannot be excluded and that hair can provide long-term histories of drug use. In some countries, persons whose driving license has been refused, revoked, or suspended for addiction to psychoactive drugs or for driving 'under the influence' can obtain a license after a medical committee has confirmed complete abstinence from illicit drugs by hair testing and has excluded any additional risk of future relapse of drug abuse (use of both clinical evaluation and hair testing). To provide objective evidence of abstinence from drugs with an acceptable chronological window in order to support the clinical decision of this medical committee, hair analysis has been included in a panel of clinical and laboratory tests, aimed at determining any drug-associated behaviors of subjects. When hair analysis and urine analysis results are compared, hair shows a much higher diagnostic sensitivity for repeated use of drugs.

Drug-Facilitated Crimes

The use of a drug to modify a person's behavior for criminal gain is not a recent phenomenon. However, the recent increase in reports of drug-facilitated crimes (sexual assault, robbery, incapacity, etc.) has caused alarm in the community. Drugs involved can be pharmaceuticals, such as benzodiazepines (flunitrazepam, lorazepam, etc.), other hypnotics (e.g., zopiclone, zolpidem), sedatives (neuroleptics, some sedating antihistamines, etc.), or anesthetics (gamma-hydroxy-butyrate, ketamine), or drugs of abuse, such as cannabis, ecstasy, or *N,N*-diethyllysergamide (LSD), or more often ethanol. Surreptitious administration into beverages such as coffee, soft drinks (cola), or even better alcoholic cocktails is relatively simple.

Most of these substances possess amnesic properties, particularly the benzodiazepines, and therefore the victims are less able to accurately recall the circumstances under which the sexual offense occurred. As they are generally short-acting, they impair an individual rapidly but only for some hours. In these situations, blood or even urine testing may not be suitable as the substance has been removed by the body. Hence, hair testing can provide evidence of prior exposure. The use of tandem MS now allows the detection of a single dose of most sedatives.

The discrimination between a single exposure and long-term use can be documented by multisectional analysis. With the concept of absence of migration along the hair shaft, a single point of exposure must be present in the segment corresponding to the period of the alleged event, using a growth rate for hair of 1 cm month⁻¹. As this growth rate can vary from 0.7 to 1.4 cm month⁻¹, the length of the hair section must be calculated accordingly. A delay of 3–5 weeks between the offense and hair collection for sectional analysis (2-cm segments) is recommended to allow the relevant hair shaft to externalize. The hair must be cut as close as possible to the scalp. Particular care is also required to ensure that the individual's hair in the strand retains the correct orientation.

Recent Trends About Contamination

Numerous applications have been described in the literature where hair analysis was used to provide evidence of either single dose or chronic drug administration and surreptitious administration of drugs to commit a crime while a person is under the influence of a drug.

The most crucial issue facing hair analysis is the avoidance of technical and evidentiary false positives. Technical false positives are caused by errors in the collection, processing, and analysis of specimens, while evidentiary false positives are caused by passive exposure to the drug. Contamination of hair through environmental exposure also has the potential to cause a false-positive result to be obtained. There are various approaches to avoid evidentiary and technical false positives. The proper washing process will not only remove surface contamination but also can provide useful information on the source of drug uptake in hair, that is, from growing hair follicle or from surface bodily fluids.

There is no consensus or uniformity in the washing procedures; however, most have similar characteristics. The agents used in washing are detergents such as shampoo, surgical scrubbing solutions, surfactants such as 0.1% sodium dodecyl sulfate, phosphate buffer, or organic solvents such as acetone, diethyl ether, methanol, ethanol, dichloromethane, hexane, or pentane of various volumes and various contact times. A single washing step is the most common procedure, although a second identical wash is sometimes performed. If external contamination is found by analyzing the wash solution, the washout kinetics of repeated washing can demonstrate that external contamination is rapidly removed. The concentration of drug in the hair after washing should exceed the concentration in the last wash by at least a factor of 10. One method involves washing hair three times with phosphate buffer prior to analysis to remove any possible external contamination and that the total concentration of any drug present in the three phosphate washes should be greater than 3.9 times the concentration in the last wash. Washing (rinsing hair) can remove drug from the interior as well as from the exterior surface of hair during the decontamination procedure.

However, it is not possible to distinguish a drug-contaminated subject from an active user. Thus, while a negative result excludes both chronic use and contact with drugs, a positive result cannot be interpreted as a sure sign of drug addiction.

The detection of drug metabolite(s) in hair, whose presence could not be explained by hydrolysis or environmental

exposure, establishes that internal drug exposure has occurred. Cocaethylene and norcocaine metabolites of cocaine meet these criteria as these metabolites are seldom found in illicit cocaine samples, and hence would not be present in hair as a result of environmental contamination. This procedure can be extended to other drugs, such as the carboxy metabolite of cannabis (THC-COOH). However, not all drugs have specific metabolites that can be detected in hair.

The presence of similar concentrations of drug in consecutive segments can be considered as indicative of potential contamination from an individual's body fluids or tissues or other forms of contamination unless it can be shown that the person was in treatment with this substance over the period represented by segments.

Whatever the result, a proper interpretation of hair results is critical and should be done ideally with other information available, for example, medical history, witness statements, and available circumstances of the matter.

Results from a single segment of hair cannot be used to discriminate long-term exposure to a drug from single exposure. This means that segmental testing is needed if a history of drug exposure is required.

It is also not possible to determine the dose of drug from a hair analysis result.

Conclusion

The value of hair analysis for the identification of drug exposure in a person is steadily gaining recognition. This can be seen from its growing use in preemployment screening, in various forensic science applications, and in clinical applications. Hair analysis may be a useful adjunct to conventional (urine, blood) drug testing in toxicology. Specimens can be more easily obtained with less embarrassment, and hair can provide a more accurate history of drug use. Gas chromatography and liquid chromatography–MS are the methods of choice for hair analysis including use of tandem MS for detection of low-dose compounds. There are still controversies on how to best interpret the results, particularly concerning external contamination, cosmetic treatments, ethnic bias, and source of drug incorporation.

Glossary

Chain of custody Ensuring evidence is secure and traceable at all times.

Postmortem redistribution Recognized toxicological phenomenon of changes in drug concentration after death.

Postmortem toxicology Analysis of drugs/poisons in specimens from deceased persons.

Introduction

The application of routine toxicology to coroners/medical examiner cases is essential in any case of a sudden or unexpected death to understand if drugs and/or poisons may have contributed to the cause of death or whether the deceased may have been under the influence of drugs at the time of death.

The suitable collection of specimens is vital to ensure that the laboratory has access to the most appropriate specimens. The interpretation of toxicology results is often the most difficult task due to variations in response from one person to another, in tolerance that develops with repeated use, and as postmortem concentrations of substances often change. Time delay between death and collection of specimen results in likely changes in concentration of drugs or poisons. The inherent chemical stability of a drug may result in that drug being transformed after death, leading to different concentrations to those just before death. Microbial or bacterially mediated changes may also result in drugs being changed after death.

This article explores these issues and provides guidance on the best practice to interpret postmortem blood concentrations.

Sample Collection and Chain of Custody

Following a sudden or unexpected death, the forensic toxicologist is recommended to undertake toxicological analysis. The common circumstances where analysis may be requested are

- after a suspected drug overdose or poisoning;
- in accident investigation – to determine whether drugs may have been a contributory factor to an accident;
- in homicide investigations – to determine whether drugs may have led to behavioral changes prior to death;
- in deaths where drugs are suspected of being misused or where compliance has led to a possible adverse drug reaction, for example, deaths in hospital.

In order to screen or quantify the concentration of a drug or poison, an appropriate specimen needs to be collected at autopsy for toxicological analysis. The choice of specimen is often dictated by the type of case being investigated as well as the condition of the body. Routine specimen collection protocols should be established by the requesting laboratory for suitable toxicology. It is the duty of the toxicologist to ensure

that the pathologist is provided with advice concerning the most appropriate samples and containers required. Whenever possible, the laboratory should provide a sample collection kit containing suitable containers, labels, and packaging to enable the pathologist to collect and submit a full range of samples and also to ensure chain of custody. It is better to collect more samples than may be required at the first post-mortem examination, rather than having to try to go back for more later.

A general outline concerning blood as a tool for toxicological analysis is presented here; however, the reader is referred to the section dealing with postmortem specimens for details of other specimens that can be collected. There are, however, a number of significant considerations that must be borne in mind when analyzing postmortem tissues that are unique to these postmortem specimens; a different approach to interpretation is warranted than that which is applied to blood samples obtained from living subjects.

It is vital that any specimen collected must be labeled, sealed, collected, and bagged separately in tamper proof containers as soon as practicable after collection. The label must include as a minimum the case number and name of deceased; additional details may include age, gender, or case type. The label must be placed over the side of the specimen (tube or pot). All specimens pertaining to a case must be collected and bagged separately in tamper proof containers. Unique numbered seals must be used for each case. The chain of custody must be preserved at all times for court purposes. Seal numbers must be recorded and appropriate sampling information pertaining to each case must be available for court purposes. If the continuity of evidence is compromised, this can result in the evidence not being admitted in court.

The identification used for all items should be retained throughout the life of the item in the laboratory. The identification system must be designed and operated to ensure that all items cannot be confused physically or when referred to in records or other documents, as well as accommodating a subdivision of groups of items and the transfer of items within and from the laboratory. A chain of custody record must be maintained by the laboratory that provides a comprehensive history of each evidence transfer such that the analysis of these specimens can be satisfactory for court purpose.

Table 1 Drugs that should be included in routine forensic toxicology investigations

Alcohol: chemically known as ethanol. Test also includes methanol and acetone ^a
Amphetamines: for example, (dex)amphetamine, methylamphetamine, 3,4-methylenedioxymethamphetamine (ecstasy), etc.
Antidepressants: for example, citalopram, sertraline, mirtazapine, etc.
Antipsychotics: for example, risperidone, olanzapine, chlorpromazine, clozapine, etc.
Benzodiazepines: for example, diazepam, temazepam, alprazolam, etc.
Cannabis: Δ^9 -tetrahydrocannabinol (THC) in blood and its metabolite in urine
Cocaine: cocaine and its metabolites
Narcotic analgesics: for example, codeine, methadone, pethidine (meperidine), morphine, oxycodone, etc.

^aAcetone can be derived from abnormal body metabolism in diabetic ketoacidotic states.

Toxicology Testing

The forensic toxicologist is primarily concerned with the analysis of biological samples from deceased persons to assist a forensic pathologist/coroner in the determination of the cause of death. The analysis of postmortem samples can be challenging, as there is often a lack of information in terms of signs or symptoms prior to the death of the individual. The type of analysis can also be compounded by little circumstantial evidence prior to the death (e.g., deceased found at home, nil suspicious circumstances, etc.). The testing of biological fluids and/or tissues for drugs and other substances is a complex process requiring sophisticated instrumentation and specialized training for staff. The request for 'toxicology' leads to series of tests, usually on blood, for a large range of over-the-counter, prescription, and illicit drugs as well as alcohol (strictly speaking ethanol). When urine is available, tests are also conducted for the presence of drugs of abuse. (These include amphetamines such as dexamphetamine, methamphetamine, ecstasy (MDMA), and several other designer amphetamines; cannabis products; cocaine; benzodiazepines; and the heroin metabolite 6-acetylmorphine.) The drugs typically included in testing, but not limited to, are shown in **Table 1**. A list of the most common drugs detected should be included as part of the toxicology report. Routine testing, that is, testing without specific indication of a particular substance, covers the common drugs but it does not include all drugs. Those drugs or poisons not tested require specific requests to the toxicology laboratory. Some examples of the drugs that may not be routinely tested but that can be relevant to cases are GHB (gamma-hydroxybutyrate), volatile substances (e.g., propane), barbiturates, and LSD (lysergic acid diethylamide).

Determination of carbon monoxide (CO) poisoning will be required when a known source of CO, such as coal gas, burnt charcoal, or automobile exhaust, is located at the scene. This is done by the measurement of CO binding to hemoglobin (as carboxyhemoglobin saturation) in blood. On the other hand, it would be of forensic interest to determine whether a fire victim had died because of CO poisoning or had already died before the fire had started. It is not possible to measure carboxyhemoglobin in severely decomposed cases or cases where blood is not available.

Poisons are sometimes an issue in death investigations. This can occur through recreational exposure by inhalation of 'solvents' (often hydrocarbons such as butane lighter fluid or fuels) or plant-derived substances (e.g., scopolamine from Angels Trumpets), accidental exposure to a substance used in the workplace, or suicidal ingestion of a poison such as strychnine, organophosphate pesticides, cyanide salts, and so on. These all require specialist tests for their detection in blood and require the laboratory to be alerted to their possible usage.

Endogenous substances such as insulin (in cases of suspected overdose), glucose (poorly controlled diabetics – vitreous humor is used for glucose measurements when a significant interval from death to sampling occurs), tryptase (marker of anaphylactic reactions), potassium (from administration errors in hospital), and so on also need to be specifically requested usually for serum analysis. Serum can only be obtained in 'fresh' bodies due to postmortem autolysis of blood. Collection of blood on admission gives a much greater likelihood of a successful collection of serum (i.e., when the body first arrives at the mortuary).

There is no universal test for all drugs or poisons. So, when the availability of tissue/samples is limited, the analysts should have all the information available to assist in conserving valuable samples for the most appropriate analyses. Access to a full case history may not only help to save valuable samples but can also save considerable time and expense in carrying out unnecessary tests. The investigating officer should therefore be required to submit as much information about the case as possible, as this may influence the type and extent of analysis undertaken as well as the interpretation of analytical results. Submitting officers should be required to provide, at a minimum, the following information:

- name of deceased;
- age;
- occupation;
- race (Caucasian, Chinese, African-American, etc.);
- date/time of discovery of body;
- date/time of death;
- date/time of postmortem;
- time between death and postmortem (postmortem interval);
- full details/case history and circumstances surrounding/leading to death;
- details of any signs or symptoms noted prior to death (e.g., diarrhea, loss of weight, delirium, drunkenness, convulsions, hallucinations, etc.);
- temperature of body surroundings/environment where body was found;
- medical history of deceased;
- availability to deceased or relatives of drugs/medicines/poisons;
- known dosages of prescription medication;
- whether deceased was a known or suspected drug user;
- whether the body was embalmed prior to autopsy;
- if death occurred following admission to hospital, the survival period between admission and death;
- the treatment/drugs/resuscitation procedures carried out before death;

- if death occurred in hospital, details of any antemortem blood samples collected (if any of these are available, they should be requested for analysis);
- whether the stomach was washed out on admission to hospital (if so, access to the stomach wash, if it is available, should be requested).

All too often a seemingly straightforward and uncomplicated death can turn into a serious case that will culminate in some form of criminal proceedings. It is far better to have all the information at hand while planning how to manage the case than to have to revisit it in hindsight or at the request of the defense lawyer. The more information that is at hand before undertaking any work, the more reasoned is the approach to analysis and interpretation will be. With the increasing availability of sensitive bench-top mass spectrometry to almost all laboratories in recent years, there has been a trend toward undertaking blood analysis alone in many cases, rather than performing analysis on a range of tissues. Historically, blood, stomach contents, liver, and urine were all used to provide a composite picture in postmortem toxicology cases. This was partly necessitated because analytical methods were relatively insensitive and necessitated a plentiful supply of material for drug extraction. In more recent years, however, toxicologists have been able to develop analytical methods that enable blood analyses to be undertaken for a wide range of drugs in small blood samples, often at concentrations significantly lower than in liver, stomach content, and urine. During recent years, the knowledge concerning what happens to drugs during postmortem, between death and the time of sampling, has grown and led many forensic toxicologists to view with caution the way that analytical results are used. If blood samples could be collected within minutes of death, the philosophy that a postmortem blood sample provides a 'snapshot' of the blood concentration of a drug at the time of death might be supportable. In reality, however, it is usually impossible to collect blood samples within minutes of death. In most cases, a considerable amount of time elapses between the moment of death and postmortem blood sampling. In the majority of cases encountered by the forensic toxicologist, the time of death and the interval elapsing between death and sampling is unknown.

Postmortem Changes in Drug Concentration

The body of a living person comprises millions of microscopic cells grouped together as tissues or organs, each with specific functions to perform. Each cell is a highly organized structure of chemical membranes, containing and controlling numerous complex chemical processes. The cells are bathed in the interstitial fluid, which provides link with the circulating blood, the function of which is to transport oxygen and essential substances around the body for the cells and to carry waste products and toxins away from the cells to specific sites in the body from where they may be eliminated (e.g., liver and kidneys). When death occurs, the mechanisms for controlling the chemical reactions within the cells cease to function. Failure of the heart to circulate blood deprives the body tissues of oxygen and other nutrients and leads to the

accumulation of waste materials in and around the cells, resulting, within a short time, in cell death. Cell death is characterized by chemical disorganization, failure of cell metabolism and cell function, and eventually a disintegration of the cell structure. As the cell walls begin to lose integrity, leakage of the cell contents into the surrounding environment takes place and out-of-control enzymes, formerly contained within the cells, start to destroy the cells and tissues in a self-destructive process known as autolytic decomposition.

After death, the temperature at which the body is stored can alter the rate of decomposition. In a body stored under refrigerated conditions, the process of autolysis and decomposition is slowed down, whereas a body maintained at an elevated temperature will be likely to decompose at a faster rate. After death, the processes that combat and protect the body from microbial infection become ineffective; hence, microbial action also contributes to the process of decomposition. As decomposition advances, drugs may be released from tissues and intracellular binding sites and diffuse from areas of higher concentration to areas of lower concentration. This offers an explanation as to why postmortem heart blood concentrations may be several orders of magnitude higher than the blood collected from the femoral vein in the upper leg. Following the consumption of a drug overdose, the liver concentrations of drugs can become very high, as this organ is one of the principal organs in the body where drugs are metabolized in preparation for their elimination. Likewise, capillary-rich lung tissue containing lipoproteins may also accumulate high concentrations of drugs. After death, drugs diffuse from the lung, liver, and other tissues where they are present in high concentrations into the pulmonary artery and vein and also into the vena cava. The diffusion process continues over time, resulting in significant variations in blood drug concentrations.

The observation that drugs are found in different concentrations at different sites in the body after death was first recorded in 1960. This observation prompted the recommendation that, ideally, peripheral blood samples should be used for toxicological analyses. It was not, however, until the mid- to late 1980s that toxicologists really began to realize the full significance of postmortem change. Several groups published a number of significant observations that have led toxicologists to express caution in interpreting postmortem blood drug concentrations. One group demonstrated that postmortem redistribution of basic drugs can occur rapidly after death and that attempts to resuscitate a corpse using cardiac massage, or even movement of the body from the site of death to the postmortem room, may influence drug distribution. As a result of their observations, the authors judged that it is unsafe to attempt to apply pharmacokinetic calculations, based on the results of a single postmortem blood analysis, to deduce the quantity of drug taken. It is also unsafe to assume that blood drawn from a peripheral site is unaffected by postmortem redistribution. Recent work has shown that drugs concentrations increase after death even if collected from a peripheral site. Pathologists or mortuary technicians must be aware that simply taking blood down the femoral vein may result in drawing blood drawn from the major vessels in the torso, such as the vena cava, where the process of diffusion from the liver or heart may be well advanced.

The ability to obtain a satisfactory peripheral blood sample at postmortem may be affected by the state of the body and blood vessels. Ideally, the femoral vein should be dissected and cut and the portion closest to the abdomen tied off with a ligature. Blood should then be collected from the leg portion of the vein, either by using a syringe or by gently massaging the vein along the leg. Many pathologists prefer to collect blood samples from the vein in the upper arm rather than the leg. However, since the subclavian vein is much closer to the heart and pulmonary blood vessels than the femoral vein, there is an increased chance that blood drawn from this site may have been affected by postmortem diffusion from the heart.

The heart is often a source of a plentiful supply of blood. However, if heart blood is collected and analyzed, peripheral blood samples must also be collected and analyzed to demonstrate whether significant differences in concentrations are present. The lungs are served with a plentiful supply of blood that can contain drugs in very high concentrations. After death, diffusion of drugs may occur from the lung into the left ventricle, resulting in blood drug concentrations in the left ventricle that are up to ten times higher than those in the right ventricle. Particular caution should be exercised in the interpretation of results when blood samples have been collected from babies. In small infants, the volume of available blood may be limited because of the body size. There is also an increased risk that samples may contain blood drawn from the major blood vessels in the torso, where the risk of contamination by hepatic blood is high. In these cases, consideration must be given to the fact that hepatic blood may contain drugs in concentrations that are orders of magnitude higher than that in peripheral blood samples.

This reinforces the necessity for toxicologists to insist that all samples are clearly labeled with respect to the site and time of sampling. Where the site of sampling is in doubt, this should be stated in the toxicology report and the interpretation should be covered by appropriate caveats. Fluid scooped from the body cavity is occasionally submitted under the description of 'blood'. Such a sample is unsuitable for interpretative purposes, as it is seldom an authentic blood sample and there is a high probability that it is contaminated with stomach content, pooled abdominal blood, bile, urine, and intestinal contents. Significant variations in drug concentrations are encountered in blood drawn from different sites of the body. Reference tables of blood drug concentrations rarely provide detailed case histories and many of these were compiled before the extent of the implications of postmortem change were realized. Those tasked with interpreting postmortem blood concentrations should therefore exercise extreme caution before expressing their views in a report or before a court of law. Caution must also be exercised when, in the case of an extremely decomposed or exhumed body, no blood is available and tissue drug concentrations are used for interpretative purposes. The practice of attempting to deduce a postmortem blood drug concentration from a tissue concentration by using tissue: blood ratios published in data collections is scientifically unsound and should not be undertaken.

Postmortem artifacts may also influence the ratios of metabolites to their parent drug in blood. For example, it has been suggested that the ratios of unconjugated to conjugated morphine might assist in indicating whether death had occurred

within a short time of the entry of the drug into the body. This philosophy proposed that if death occurred rapidly after entry of morphine or heroin into the body, the concentration of unconjugated morphine present in blood would be higher than the conjugated morphine concentration. The volume of distribution of morphine is, however, large compared with that of morphine glucuronides. Hence, while only a small proportion of morphine is present in the circulating blood, a significant proportion of the morphine glucuronides are present in blood. Any factors that could change the distribution of morphine, or cause the conversion of some or all the morphine glucuronides back into morphine, could grossly affect the interpretation of results based on morphine:morphine glucuronide ratios and subsequently provide an erroneous conclusion with respect to time of dosing in relation to death.

There are many compilations of postmortem blood drug data that have been associated with fatal poisoning. However, it must always be remembered that in many cases, blood drug concentrations cannot be interpreted in isolation and the task of interpretation should only be undertaken after full discussion has taken place between the toxicologist and the pathologist.

Most experienced toxicologists will have encountered cases where the so-called 'fatal blood concentrations' have been measured in a deceased person, but the cause of death was not directly associated with the drug detected. Drug addicts and palliative care patients can build up considerable tolerance to drugs such as opiates and appear to behave relatively normally, while the concentrations of opiates in their blood would be capable of causing death in a nontolerant subject. It is also well known that in many cases, the cause of death may be directly attributed to gunshot wounds, stabbing, or road traffic accidents, but concentrations of drugs in blood fall within the range of concentrations associated with fatal poisoning. Our knowledge of postmortem change and the effects that may be associated with it is still far from being complete. However, an awareness that such phenomena exist should provide a warning to toxicologists and pathologists that the process of interpreting postmortem blood results is not simple. Because of the problems associated with drug tolerance and postmortem movement of drugs, all that can be safely deduced from a blood drug concentration alone is that the drug or its metabolites are present. A more elaborate interpretation should only be reached after all the factors in a case have been drawn together, including the histological evidence, the gross pathology, the known circumstances of the case, and the medical history of the deceased.

Introduction

Analyses of drugs of abuse in biological media have been mainly associated with death investigation and criminal prosecution of those accused of driving under the influence of alcohol. In the United States of America (US), urine drug testing has recently become widely used as a deterrent tactic in combating drug abuse: in the military, the criminal justice system, and later in the workplace. In the aviation industry, urine drug testing is a common practice worldwide. As a result of the North American Free Trade Agreement, workplace urine drug testing is now extended beyond the US border. Recently, the government of Taiwan has also implemented urine drug testing programs in schools, the workplace and in the criminal justice system. These practices have dramatically increased the number of tests and the use of urine as the test specimen.

The *Mandatory Guidelines for Federal Workplace Drug Testing Program*, published by the US Department of Health and Human Services on 11 April 1988, and its updated versions, formulated the mechanisms by which the National Laboratory Certification Program oversees civilian drug testing activities in the US. These guidelines, and previously established military directives, adopt urine as the routine specimen for testing the following drug categories: amphetamines, barbiturates, benzodiazepines, cannabis, cocaine, lysergic acid diethylamide, methadone, methaqualone, opiates, phencyclidine, and propoxyphene. (To the authors' knowledge, no random urine drug testing program included all of these drug categories.)

Test methodologies adopted by these testing programs normally include an immunoassay (preliminary or initial test), followed by confirmatory gas chromatography–mass spectrometry (GC-MS) analysis of the drug tested positive by the immunoassay. In a workplace drug testing program, test results are initially considered (within the laboratory) presumptive 'positive' or 'negative' – terms that do not hold the same meanings as commonly defined in the laboratory for scientific measurements. Universal administrative cutoff values, rather than scientific and statistical detection limit data established by individual laboratories, are used as the basis for determining whether a specimen is (presumptive) positive or negative (of the preliminary test). Those considered positive are further tested using a GC-MS protocol, again using a universal administrative cutoff concentration of the targeted analyte as the basis for deciding whether a specimen can be reported as positive. Cutoff values adopted by the US workplace and the military drug testing programs are shown in [Table 1](#).

Urine Specimen Characteristics and Specimen Integrity

Specimen Characteristics

Compared with blood, urine is relatively free of protein, thus making it possible for direct extraction. Urine also contains high concentrations of metabolites and provide a longer detection time for most drugs. Thus, urine is a preferred specimen for monitoring drug exposure (within a certain time window) of a large population on a regular basis.

Since certain drugs may not be found (or detected in low levels) in urine, while found in liver and blood samples in intoxicated concentrations, urine screen alone may not be sufficient for systematic toxicological analysis. Furthermore, blood is a better specimen for impairment or toxicological assessment purposes, as it is most closely related to drug concentrations at the effector sites.

Urine drug testing results depend on factors such as the time lapse between specimen collection and drug intake, and urine pH. For example, diet that causes urine pH changes may significantly alter the excretion patterns of certain drugs. Thus, weakly basic drugs (such as amphetamine) are more efficiently excreted in acid urine, whereas weakly acidic drugs (such as barbiturates and salicylates) are more efficiently excreted in alkaline urine.

Specimen Integrity

Factors that may compromise specimen integrity, thus affecting test results, include:

- substitution of a nonurine liquid or urine from a different person;
- addition of an adulterant rendering the specimen unsuitable for certain test methodologies;
- the presence of certain characteristics associated with the specimen container or storage conditions.

Implementation of proper chain-of-custody procedures can best safeguard the integrity of a specimen. Laboratory procedures described later are often used to evaluate specimen integrity; they are, however, not always effective.

Specimen origin identification

Analysis of blood group antigens and polymorphic proteins may help exclude a specific person as the specimen donor. These approaches are often ineffective owing to their low discrimination power and the large sample size required.

Table 1 Cutoffs^a of immunoassay and GC/MS test adopted by the US certification programs

Drug	Immunoassay (ng ml ⁻¹)			GC-MS (ng ml ⁻¹)		
	Analyte targeted	DoD	HHS	Analyte targeted	DoD	HHS
Amphetamines	Amphetamines	—	1000			
	Amphetamine	500	—	Amphetamine	500	500
	Methamphetamine	500	—	Methamphetamine	500	500 ^a
Barbiturates	Secobarbital	200	—	Amobarbital	200	—
				Butalbital	200	—
				Pentobarbital	200	—
				Secobarbital	200	—
Cocaine	Benzoyllecgonine	150	300	Benzoyllecgonine	100	150
Marijuana	9-THC-COOH	50	15	9-THC-COOH	50	15
Opiates	Morphine	300	300	Codeine	2000	2000
				Morphine	4000	2000 ^b
				6-MAM	10	10 ^b
Phencyclidine	Phencyclidine	25	25	Phencyclidine	25	25
LSD	LSD	0.5	—	LSD	0.2	—

DoD, US Department of Defense drug testing program; HHS, US Department of Health and Human Services, National Laboratory Certification Program; 9-THC-COOH, 11-nor- Δ^9 -tetrahydrocannabinol-9-carboxylic acid; 6-MAM, 6-monoacetylmorphine; LSD, lysergic acid diethylamide.

^aFor administrative purposes, a sample is considered negative if the concentration of the target analyte is lower than the listed 'cutoff' value. It is also commonly practiced that a sample is considered positive only if ≥ 200 ng/ml amphetamine is also present.

^bTesting of 6-MAM is required only when the concentration of morphine is ≥ 2000 ng ml⁻¹.

DNA-based technologies can be more effective. Squamous and transitional epithelial cells from the urinary tract often provide adequate DNA for specimen identification purposes. Since restriction fragment length polymorphism methods require larger DNA fragments and sample size, methods based on polymerase chain reaction offer higher success rates. Various genotypes of six markers that can be determined by a commercial kit are shown in Table 2.

Specimen adulteration and evaluation parameters

Specimens can be adulterated *in vivo* through the use of diuretics (or simply a large volume of liquid), pH-altering liquids, or materials that cause the excretion of test-interfering substances. *in vitro* adulterations using household products are most widely reported events. These products often affect immunoassay test results. Some adulterants may actually destroy analytes, resulting in negative GC-MS test results.

It is often difficult to distinguish between an adulterated urine and a genuine one that respond marginally towards tests implemented to monitor parameters indicative of adulteration, such as specific gravity, pH, and creatinine level. Selecting appropriate cutoff values of these parameters, that can best identify presumptive positive adulteration specimens for further confirmatory identification of adulterant, is no trivial matter. For example, adopting 1.007–1.035 specific gravity range and >45 mg dl⁻¹ creatinine content as integrity criteria resulted in 69 (47.9%) out of the 144 highly suspicious urine specimens evading detection.

Obviously, the most effective evaluation parameter varies with the adopted method of adulteration. Indicative parameters include temperature, color and smell, pH, and contents

Table 2 Genetic markers and allele frequencies^a using the PM + DQA1 typing kit

Marker	Allele	Frequency ^a

of additional substances, including diuretics, household items, and chemicals such as nitrite and glutaraldehyde, reportedly being specifically formulated for urine adulteration purposes.

Analyte stability

Stability of the analytes during the postcollection period may affect the quantitative data and the interpretation of these results. Important factors affecting the stability of an analyte include pH variations caused by intrinsic and extrinsic specimen characteristics; container properties, and other storage conditions such as light and temperature; and the presence of oxygen, preservatives, and other foreign substances.

Application of Immunoassays to Urine Drug Testing

Immunoassays are adopted as the 'official' preliminary test method in workplace urine drug testing programs because they are sensitive (without requiring pretreatment), can be automated and are based on an underlying principle that is different from the confirmatory GC-MS methods.

Common Immunoassays

Most immunoassay procedures adopt the competitive binding principle, in which the antibody is allowed to react with a mixture of labeled (control) and unlabeled (sample) drugs. The presence and the quantity of a drug in the sample is evaluated on the basis of the quantities of the labeled drug in the reacted or unreacted forms. The control drugs are labeled in different ways, each requiring different methods of detection and quantification. For example, radioactive isotopes, such as ^{125}I , are used for labeling in radioimmunoassay (RIA) methods; active enzymes, which are capable of converting (indirectly) nicotinamide adenine dinucleotide (NAD) to its reduced form (NADH), are coupled to the drug in enzyme-multiplied immunoassay techniques (EMIT); fluoresceins are coupled to the drug used in fluorescence polarization immunoassay (FPIA); and particles are attached to the drug in particle immunoassay (PIA).

An immunoassay system is considered heterogeneous if a phase-separation step is needed prior to detection. The detection process is designed to measure the extent of the labeled antigen linked (directly or indirectly) to the antibody, thus reflecting the amount of the test drug (unlabeled antigen) in the sample. Methodologies based on the measurement of radioactivity are heterogeneous because the detecting device cannot differentiate the source of the radioactivity (free or bound labeled antigen). Therefore, a separation step is required.

Methodologies based on a change in optical intensities do not require the separation step if these properties are modified through the substrate's linkage (directly or indirectly) to the antibody. They are considered homogeneous immunoassays. Both heterogeneous and homogeneous immunoassays are used for workplace drug urinalysis.

Interferences and Cross-reactivity

Interference can be broadly defined as the cause for a test result that does not provide the intended diagnostic finding reflecting the true status of the specimen. The following conditions may generate test results leading to incorrect interpretation of the specimen status:

- the presence of the targeted analyte derived from sources other than the targeted drugs of abuse;

- the presence of cross-reacting compounds with known or unknown structures;
- specimen conditions that cause nonspecific binding or interfere with the assay's detection mechanism;
- the presence of adulterants that degrade the analytes or alter their interacting characteristics.

Targeted analytes from legal sources

Some of the analytes targeted as indicators of drug abuse may derive from unintended exposure, food consumption or licit medication. For example, it is well known that morphine and codeine may be observed in urine specimens collected from individuals consuming food items with poppy seeds or prescriptions containing morphine or codeine. Methamphetamine and amphetamine can derive from the use of Vicks nasal inhaler and a substantial number of licit drugs.

Cross-reacting compounds

Cross-reacting compounds are widely reported and many are listed in reagent inserts or documentation provided by the manufacturers. Identities of most reported cross-reacting compounds are known, while others are not. For example, it has been reported that unknown metabolites of chlorpromazine, brompheniramine, and labetalol caused EMIT d.a.u. Monoclonal Amphetamine/Methamphetamine Assay to generate false-positive results. Metabolites, not the parent drugs, are believed to be the responsible cross-reacting compounds because:

- these drugs were prescribed for urine specimen donors;
- these parent drugs were present in the urine specimens;
- studies on control samples with various concentrations of the parent drugs *alone* failed to generate a positive result.

Since reference metabolites of these drugs are not available, the exact cross-reacting metabolites cannot be identified.

Nonspecific binding

Many postmortem urine specimens reportedly produced absorbance change values lower than those resulting from negative calibrators and specimens collected from healthy persons. This is attributed to the presence of nonspecific interacting materials that cause a higher initial absorbance value.

Detection mechanism

Enzyme immunoassay methods are most likely to suffer spectrometric interference caused by other substances present. Listed below are some examples:

- *p*-Nitrophenol (a metabolite of methyl parathion) and tolmetin (a nonsteroidal anti-inflammatory drug) and its metabolites can absorb strongly in the 340 nm region at pH 8.0 and thus cause interference.
- The presence of metronidazole or mefenamic acid causes excessively high initial absorbance values, thus preventing the assessment of EMIT test data.
- Salicylic acid (the principal metabolite of aspirin) interferes with the EMIT test methodology by reducing the molar absorptivity of NADH at 340 nm.

Table 3 Effect of various adulterants on immunoassays for drugs of abuse

Adulterant	Amphetamines	Barbiturates	Benzodiazepines	Cocaine	Opiates	Phencyclidine	Marijuana
Ammonia							+R
Ascorbate							−R
Bicarbonate	−R	−R			−E	−F	
Bleach	−R; −E; −F; −C	−C	−E; −C	−C	−R; −E; −F; −C	−R; −E; −F; −C	−E; −F; −C
Detergent	−C	+F; −C	−C	+F; −C	−C	−C	
Drano	−E; −C	−E; −C	−E; −C	−R; −E; −F; −C	−E; −C	−C	−R; −E; −C
Golden seal	−C		−F				−R; −E; −C
Hand soap	+F	+F	−E				−R; −E
Joy	+F	+F	+R; −E; +F		−E		+R; −E; +F
Lime	−R				−R		−R
Peroxide			−E; +F				
Phosphate				−R −F	−F	−R	
Salt (NaCl)	−E	−E	−E	−E	−E	−E	−E
Vanish	−R				−R		−R
Vinegar							−E; −F
Visine			−E				−R; −E; −C

Adulterant reduces (−) or increases (+) response to drug listed by methodology. R, radioimmunoassay; E, enzyme multiplied immunoassay technique; F, fluorescence polarization immunoassay; C, cloned enzyme donor immunoassay.

Adulterants

Adulterants may actually destroy the targeted drugs, thus rendering the specimen 'truly' negative, while most adulterants cause nonspecific binding or create interference to the targeted antibody–antigen reaction or the detection mechanism.

Many household products are known to affect the responses of common immunoassays. Results from an exemplar study are shown in Table 3. Most interference studies did not compare the effects of adulterants on various immunoassays under the same conditions; it is therefore difficult to make general statements concerning the robustness of one methodology over the others. It seems to be clear, however, that cannabinoid assays are more susceptible to the interfering effects of adulterants.

Numerous mechanisms have been proposed to account for the observed interference, but exact causes are generally unknown. It has been proved, however, that bleach actually causes the degradation of 9-THC-COOH. Visine was believed to increase the adhesion of 9-THC-COOH to the borosilicate glass specimen containers, thereby reducing the availability of 9-THC-COOH in antibody-based assays.

Application of GC-MS in Urine Drug Testing

Confirmatory test procedures for drugs of abuse in biological media often include acid, base, or enzyme hydrolysis; liquid–liquid or solid-phase extraction; and often with derivatization. Selective ion monitoring (SIM) GC-MS protocols are used almost universally for the analysis of the limited number of drugs/metabolites targeted by workplace drug testing programs.

Sample Pretreatment

Many free drugs (and their metabolites) have strong affinity to proteins, whereas most conjugates are highly hydrophilic and not amenable to extraction by organic solvents. Thus,

pretreatment procedures generally include the hydrolysis of drug conjugates (if present), the removal of the binding proteins, and the extraction of the drugs from the resulting reaction mixture. Since urine has limited protein content, protein removal is generally not a critical step.

Acid and enzyme hydrolysis of conjugated drugs

Both acid hydrolysis and enzyme digestion have their merits. For example:

- β -glucuronidase is known to release intact benzodiazepines from their glucuronide conjugates without converting to their corresponding benzophenones, which is a typical product of acid hydrolysis.
- compared to β -glucuronidase, acid hydrolysis of morphine glucuronide is less time-consuming and can achieve a higher recovery rate. However, this process tends to cause the decomposition of acidlabile compounds in the matrix, leaving a dirty reaction mixture.

Enzyme hydrolysis may be preferred when the analyte is acidlabile and high recovery is not an important factor, i.e. when sensitive detection and quantification methodologies are incorporated in the overall protocols.

Extraction

An extraction step typically removes interfering materials and concentrates the analyte (through reconstituting the extraction residue into a small volume of suitable solvent prior to final instrumental analysis).

Liquid–liquid extraction systems are designed to have the analyte partition preferably into the organic phase in its unionized form or as an ion pair. The analyte may also be 'salted out' of the aqueous phase into the organic one by greatly increasing the ionic strength of the former using a high concentration of electrolytes. pH adjustment of the sample or the addition of a proper counterion may be used to facilitate a favorable

partitioning of the drug in its unionized form or as an ion pair, respectively.

In a solid-phase extraction process, separation is performed with a solid additive or column material using hydrophilic, hydrophobic, or ionic groups attached to silica. Solid-phase extraction approaches offer the following advantages over conventional liquid–liquid procedures:

- less organic solvent usage;
- no foaming problems;
- shorter sample preparation time;
- ease of incorporation into an automatic operation process.

Solid-phase extraction procedures now widely adopted for the analysis of drugs of abuse in urine, include four basic operational steps: conditioning, loading, rinsing, and eluting. The first solvent for conditioning should be as strong as, or stronger than, the elution solvent. The second conditioning solvent should be the same as, or as close to the strength of, the loading solvent as possible. The solvent used for loading should be as weak as possible to produce the tightest or narrowest band of adsorbed sample on the sorbent. A solvent that is slightly stronger or of the same strength as the loading solvent, is used as the rinse solvent. The rinse will elute unwanted sample components that are not as strongly retained as the analytes, and also wash down small droplets of loading solvent adhering to the walls of the tube to ensure that all sample come in contact with the sorbent. An ideal eluting solvent should elute the analytes within 5–10 bed volumes. The optimal amount of solvent to elute the analytes from a 500 mg cartridge is about 0.6–1.2 ml. Using a solvent that is too strong will result in the elution of unnecessary sample components that are more strongly retained than the analytes, whereas a solvent that is too weak will result in excessive elution solvent volumes, which negate the advantage of reducing solvent consumption with solid-phase extraction cartridges. Sometimes, a desired solvent strength may have to be obtained by blending appropriate amounts of miscible solvents.

If a water-immiscible eluant is selected and the final analysis is to be performed with GC, a ‘drying’ procedure should be applied between the rinsing and the eluting steps. It has been reported that the combination of vacuum and a small amount of methanol can produce a ‘dry’ eluate without causing a substantial loss of drugs.

Chemical Derivatization

Many drugs/metabolites are derivatized, prior to the measurement step, to bring the analytes to the chemical forms that are compatible with the chromatographic environment or to maximize their chromatographic separation and detection efficiencies. For example, derivatizations are carried out to improve the analyte’s volatility; to eliminate active functional groups that may cause undesired interactions with the chromatographic components, resulting in peak loss (due to irreversible adsorption) or peak tailing (caused by reversible adsorption); and, through the use of a chiral agent, to achieve resolution of enantiomeric components.

Derivatization is also an effective approach to achieve higher detection or quantification efficiency or to facilitate analyte structure elucidation. For example, the hydroxy group

in oxazepam is derivatized to prevent ring contraction that may occur at elevated temperatures. In GC-MS applications, mass shifts in the spectra produced by different derivatizing agents can reveal valuable information concerning the functional groups in the analyte.

Qualitative Analysis

Serving as a chromatograph detector, a mass spectrometer (MS) provides valuable ‘fingerprint’ information by resolving and displaying charged particles originated from chromatograph eluates. Together with the chromatographic retention data, the MS detection provides test results that are normally considered conclusive for analyte identifications. MS detector also facilitates adoption of an isotopic analog of the analyte as the internal standard in an analytical protocol.

Serving as an internal standard, an isotopic analog of the analyte incorporated at the very early stage of the analytical process, serves as a model compound which, through its detection at the final step, provides a mechanism to prove successful completion of the entire analytical protocol. (Verifying a successful protocol is essential when the targeted analyte is not detected in the test sample.) Internal standards also provide intrasample retention time and ion intensity data that help analyte identification and quantification.

In general, fully credible qualitative analysis (as opposed to target-compound analysis) require operating the MS in full-scan mode. The resulting spectra are then compared with those in the database or with an in-house standard; together with the GC retention data, analyte identification is often conclusive.

Data collection using SIM mode can provide enhanced sensitivity and is commonly used as an integral part of a well-designed target compound analysis (qualitative and quantitative) scheme. Without the benefits of complete spectra, the use of SIM data for qualitative determination purposes should be exercised with extreme caution. For example:

- As many ions that are characteristic of the analyte should be selected. Ideally, the molecular ion should be used if it exists with a reasonable intensity. If the analyte is derivatized with a derivatizing reagent prior to the GC-MS analysis, at least one of the ions selected should include the complete or a characteristic moiety of the analyte. The exclusive use only of ions that are derived from the derivatizing reagent is not acceptable.
- The intensity ratios of the selected ions should be closely monitored and compared with the corresponding ratios obtained from a standard (or control) that is analyzed under identical conditions.
- The retention times of all ions monitored for the analyte should be coincidental. In addition, the retention time and ion intensity ratios of the internal standard should be compared to the corresponding data of the analyte. This ‘intra-sample’ information further improves the certainty of an identification.
- This approach should only be applied to well-studied systems in which isotopic analogs of the analytes are normally available and incorporated in the analytical process. Furthermore, GC operational conditions should be optimized so that closely related compounds are chromatographed with distinguishable retention data.

Considering the fact that the identified analyte has also survived the chemical processes (hydrolysis, extraction, and derivatization) designed for the targeted drug and proven effective for the internal standard (often a deuterated analog with chemical properties practically identical to the analyte), the above identification criteria should not reach an incorrect conclusion if executed by an able analyst.

Quantitative Determination

Although MS by itself is not necessarily the most quantitative detector for a chromatographic system, the use of an isotopic analog as the internal standard, alleviates the effects of many variations in the analytical process, thus often providing the best overall quantitative result.

Internal standard

Deuterated analogs of the analytes are now commonly used internal standards for the quantification of drugs in biological matrices. However, not all deuterium-labeled isotopic analogs (of the analyte) are effective. Since the analyte and the internal standard are rarely separated adequately, the proposed isotopic analog must generate at least one (preferably two or three) ions relatively free of cross contribution by the analyte. There must also be at least three ions designated for the analyte that are relatively free of cross contribution by the proposed internal standard. If these requirements are not met, quantitative results and the ion intensity ratio data (which are commonly used as important parameters for analyte identification) may become unreliable.

Calibration approaches

A typical quantitative GCMS protocol involves monitoring several selected ions from the analyte and the isotopic analog. Quantification is achieved by comparing a selected analyte-to-isotopic analog ion intensity ratio observed from the test specimen and the same ratio observed from the calibration standard. The calibration standard contains the same amount of the internal standard and a known amount of the analyte and is processed in parallel with the test specimen. The analyte concentration in the test specimen can be calculated using a one-point calibration approach, as shown in Figure 1.

This procedure can be used to determine directly the analyte concentration in a test specimen (one point calibration) and has proven highly effective when the concentration of the analyte is in the immediate vicinity of the single calibrator's concentration. Alternatively, the ion intensity ratio data can be used to determine the responses of a set of standards, from which a calibration curve is established and used for analyte

concentration determination in a test specimen (multiple-point calibration). Multiple-point calibration approaches can be implemented with different regression models, including linear or nonlinear; weighted or unweighted; and whether or not to force the regression through the point of origin.

It has been shown that multiple-point nonlinear calibration can provide a wider calibration range. Empirical studies also indicate that one-point calibration quantification results for pentobarbital were actually inferior to those obtained for the other three barbiturates – even though *d*₅-pentobarbital was used as the single internal standard for all analytes. Factors that should be carefully evaluated include:

- cross contribution of quantification ions selected for the analyte and the internal standard;
- selection of an appropriate calibration model to take into account the cross contribution interference – a common phenomenon.

Instrumental parameters

For best accuracy and precision of SIM measurements, instrumental parameters like instrument resolution, ion-monitoring position, threshold setting and dwell time, must also be carefully considered. Instrument drift from the peak center and the fluctuations in intensities of the selected ion beams will affect measurement precision, mainly because of the greater variation in the intensities of the weaker signals detected. Improper threshold settings will also affect the weaker signals to a greater extent. To achieve the best results, the signal level of the internal standard should be comparable to that of the analyte.

For GC-MS applications, problems associated with differences in ion residence time in the ion source must also be addressed. To assure adequate accuracy, the number of data points that define an ion chromatographic peak must be sufficient, preferably about 20. Because ions are sequentially monitored, the number of data points for a GC peak depends, not only on the chromatographic peak width, but also on the ion-monitoring cycle time. The cycle time depends on the number of ions monitored, the time spent on monitoring each ion (dwell time) and the 'overhead time' needed by the system for effective switches.

Application Examples

The implementation of workplace testing programs prompted the development of many robust extraction–derivatization GC-MS procedures for routine and large-scale analysis of targeted drugs in urine specimens. Examples of these protocols are summarized in Figure 2. Evaporated residues are reconstituted and analyzed using GC-MS parameters shown in Table 4. Qualitative and quantitative determination criteria described in earlier sections are used for these procedures.

Correlation of Immunoassay and GC-MS Test Results

Conventional immunoassay reagents are typically not very specific. In fact, cross-reactivity to drugs with similar structures

$$\frac{\left[\begin{array}{c} \text{(Selected ion intensity)}_{\text{Analyte}} \\ \text{(Selected ion intensity)}_{\text{Internal Std}} \end{array} \right]_{\text{Test sample}}}{\left[\begin{array}{c} \text{(Selected ion intensity)}_{\text{Analyte}} \\ \text{(Selected ion intensity)}_{\text{Internal Std}} \end{array} \right]_{\text{Calibration standard}}} \times \left[\begin{array}{c} \text{Standard} \\ \text{conc.} \end{array} \right]_{\text{Calibration standard}} = \left[\begin{array}{c} \text{Analyte} \\ \text{conc.} \end{array} \right]_{\text{Test sample}}$$

Methadone	Ethyl acetate (20 µl)		223, 294, 295; 226, 297	223/294, 295/294; 226/297	300

MDMA, 3, 4-methylenedioxymethamphetamine.

^aSome of these drugs/metabolites were analyzed as derivatives using methodologies shown in Figure 1. *N*-Trifluoroacetyl-*l*-prolyl chloride was used for enantiomeric composition analyses of amphetamines.

^bItalic ions are used for quantification.

^c¹-Phenyl-2-aminopropane-1,2,3,3,3-*d*₅, 1-phenyl-2-(methyl-*d*₃-amino)propane-1,1,2,3,3,3-*d*₆, 1-(3,4-methylene-dioxy)phenyl-2-(methylamino)propane-1,2,3,3,3-*d*₅, pentobarbital-5-ethyl-*d*₅, 11-nor- Δ^9 -tetrahydrocannabinol-9-carboxylic acid-5'-*d*₃, benzoylcegonine-*N*-methyl-*d*₃, codeine-*N*-methyl-*d*₃, morphine-*N*-methyl-*d*₃, phencyclidine-phenyl-*d*₅, oxazepam-phenyl-*d*₅, and methadone-1,1,1-*d*₃ are used as the internal standards for respective analytes.

^dFor administrative purpose, a sample is considered negative if the concentration of the target analyte is lower than the listed 'cutoff' value. It is also common practice for a sample to be considered positive only if ≥ 200 ng ml⁻¹ amphetamine is also present.

Courtesy of the American Chemical Society.

can be advantageous in general applications. It is, however, a significant disadvantage when used in workplace drug testing programs, in which a positive result is reported only if the GC/MS result (of a targeted drug/metabolite) is at or above a cutoff concentration, and the prior immunoassay screen test result is also at or above an identical or higher cutoff level. Thus, manufacturers often strive to reduce a reagent's cross-reacting characteristics and improve the detection mechanism so that immunoassay test results can be more comparable with GC-MS, thereby improving the overall test efficiency. The ideal situation is that all samples screened positive are confirmed to contain the target drug/metabolite at or above the GC/MS cutoff level, while those screened negative contain no (or below GC/MS cutoff) targeted drug/metabolite.

Because immunoassay reagents are not absolutely specific, the ideal situation can never be realized. One can hope, however, for an immunoassay to respond sensitively toward variations of the analyte content, especially in the vicinity of the selected cutoff concentration. Furthermore, the immunoassay responses should correlate reasonably with the GC-MS results. The appropriate relationship between the cutoffs set for these two tests depend on the metabolites distribution pattern of the

drug and the cross-reactivity characteristics of the adopted immunoassay.

Testing for marijuana use serves as an excellent example to illustrate the importance of cutoff selection when using an immunoassay as the preliminary test for GC-MS analysis. With a specific cutoff adopted for the GC-MS test, overall positive rate varies with the cutoff level adopted for the immunoassay. Immunoassay cutoffs that best correspond to a specific GC-MS cutoff varies with the type, the manufacturer, and the lot of the adopted immunoassay.

Issues in the Interpretation of Urine Drug-Testing Results

It has been widely publicized that urine specimens tested positive for opiate and amphetamine may actually be caused by the use of licit medication or food items. For the opiate drug category, it is possible to confirm heroin use if 6-monoacetylmorphine is detected. Concentrations of morphine and codeine and their ratio can also provide useful, but often inconclusive, information.

Detection of methamphetamine as an analytical artifact has been attributed to the presence of high level of ephedrine or pseudoephedrine in urine specimens. It is thus recommended that a urine specimen cannot be reported positive for methamphetamine without the presence of amphetamine.

Amphetamine and methamphetamine may derive from the use of Vicks nasal inhaler and other medicines. For example, amphetamine is available as Dexedrine, which consists solely of dextroamphetamine (*d*-amphetamine), and benzphetamine, which consists of equal amounts of *d*-amphetamine and racemic (*d,l*-) amphetamine. Amphetamine and methamphetamine may also be present as metabolites of other drugs (precursors), such as amphetaminil, benzphetamine, clobenzorex, deprenyl, dimethylamphetamine, ethylamphetamine, famprofazone, fencamine, fenethylline, fenproporex, furfenorex, mafenorex, mesocarb, and prenylamine. Since amphetamine and methamphetamine derived from these drugs have certain enantiomeric composition characteristics, enantiomeric analysis can often provide valuable information, but not always with definite conclusions.

Unintended passive inhalation of marijuana and cocaine can also result in the detection of the metabolites normally monitored to indicate the abuse of these drugs. The detection of cocaine metabolite has also been attributed to drinking Health Inca Tea, handling of cocaine-containing currency, and skin absorption for those who are exposed to cocaine at their work environment. Analyte concentrations resulting from drug exposure are generally low; claims should be evaluated carefully on a case-by-case basis. Opinions are often offered; definite conclusions are not always achievable based on test results alone.

Acknowledgments

We are grateful to the Taiwanese National Science Council for providing a visiting appointment (NSC87-2811-B-043A-0001) to Ray H Liu, which greatly facilitated the preparation of this publication.

Introduction

Chemical spot tests (CSTs), sometimes referred to as color tests, provided toxicologists and criminalists with one of the earliest tools for the presumptive identification of drugs and poisons. These tests continue to be popular for several reasons. They rely on simple chemical reactions and produce visible results that can be interpreted with the naked-eye. The reagents and laboratory materials needed to perform the tests are inexpensive and readily available. The tests can be performed by technicians without extensive training. Since the tests require minimal reagents and materials, small and even on-site laboratories can perform the tests. They can also be employed in the field by law enforcement agents. The utility of these tests is demonstrated by the fact that even today, when the use of sophisticated analytical instrumentation is so pervasive, they are still an integral part of the testing arsenal of forensic laboratories.

In two US National Institute of Justice (NIJ) standards, NILECJ-STD-0604.00 and NILECJ-STD-0605.00, the procedures for the use and validation of eleven different chemical spot-testing reagents were described. To better address the current needs of drug testing laboratories, the information in these documents was reviewed and updated or revalidated as needed. The need to include additional tests/analytes or remove existing tests/analytes from the original standards was assessed. An informal questionnaire addressing the use of these CSTs in forensic laboratories was mailed to approximately 325 laboratories/individuals selected from the rosters of American Society of Crime Laboratory Directors (ASCLD), the Regional Association of Forensic Scientists and the Criminalistics Section of the American Academy of Forensic Sciences (AAFS). This mailing was performed in a semi-random fashion with an attempt to contact at least two laboratories or drug chemists in each state and to include the regional Drug Enforcement Administration laboratories. We received 121 responses. They indicated that CSTs are still frequently used by 86% (104) of the responding laboratories. Greater than 90% of these laboratories used at least four of the tests; cobalt thiocyanate for cocaine, Duquenois-Levine for marijuana, Marquis for many basic drugs and *para*-dimethylaminobenzaldehyde (*p*-DMAB) for LSD. Ten of the CSTs described in the NIJ documents were still routinely used by more than one third of the laboratories. Twenty-five percent of respondents suggested adding the Simon's or nitroprusside test for the detection of secondary amines, such as methamphetamine and methylenedioxymethamphetamine,

to the battery of spot tests described in the original NIJ documents. Additional drugs that had become more prevalent since the publication of the standards such as acetaminophen, alprazolam, diazepam, ephedrine, hydrocodone, and pseudoephedrine were added to the original list of analytes to be tested. This article reviews the data presented in the two original NIJ documents and presents new validation data for an expanded list of drugs using 12 CSTs.

Materials and methods

Chemicals

Cobalt thiocyanate, cobalt acetate dihydrate, glacial acetic acid, isopropylamine, acetaldehyde, ammonium vanadate, formaldehyde, *para*-dimethylaminobenzaldehyde, ferric chloride, vanillin, sodium molybdate, selenious acid, copper sulfate pentahydrate, sodium nitroprusside, 2-chloroacetophenone, and sodium carbonate were purchased from Sigma-Aldrich Chemical (St. Louis, MO, USA). Methanol, hexane, and chloroform were obtained from Burdick and Jackson (Muskegon, MI, USA). Hydrochloric acid, sulfuric acid, nitric acid, and pyridine were purchased from Mallinckrodt Baker, (Paris, KY, USA). Ethanol was obtained from Quantum Chemical (Tuscola, IL, USA). The drugs were purchased in powder form from Sigma-Aldrich Chemical (St. Louis, MO, USA), Alltech-Applied Science (State College, PA, USA) or Research Triangle Institute (RTI, NC, USA).

Materials

Porcelain plates with 12 wells, glass culture tubes (12×75 mm) and Pasteur pipettes were purchased from VWR Scientific Products (Denver, CO, USA). The Munsell Book of Color (Volumes 1 and 2) were purchased from GretagMacbeth (New Windsor, NY, USA). The centroid color charts, published by the Inter-Society Color Council and the National Bureau of Standards, were obtained from Nick Hale (Naples, FL, USA).

CST Procedures

The procedures for preparing the CST reagents and performing each test are described below. One or two drops of reagent(s) were added to the drug using a Pasteur pipette unless otherwise noted.

A. 1 Cobalt thiocyanate

Dissolve 2.0 g of cobalt (II) thiocyanate in 100 ml of distilled water.

*Received 23 November 1999; accepted 10 December 1999

[†]Corresponding author

A. 2 Dille–Koppanyi reagent, modified

Solution A: Dissolve 0.1 g of cobalt (II) acetate dihydrate in 100 ml of methanol. Add 0.2 ml of glacial acetic acid and mix.

Solution B: Add 5 ml of isopropylamine to 95 ml of methanol.

Procedure: Add two drops of solution A to the drug, followed by one drop of solution B.

A. 3 Duquenois–Levine reagent, modified

Solution A: Add 2.5 ml of acetaldehyde and 2.0 g of vanillin to 100 ml of 95% ethanol.

Solution B: Concentrated hydrochloric acid.

Solution C: Chloroform.

Procedure: Add three drops of solution A to the drug and shake for 1 min. Then add three drops of solution B. Agitate gently, and determine the color produced. Add nine drops of solution C and note whether the color is extracted from the mixture to A and B.

A. 4 Mandelin reagent

Dissolve 1.0 g of ammonium vanadate in 100 ml of concentrated sulfuric acid.

A. 5 Marquis reagent

Carefully add 100 ml of concentrated sulfuric acid to 5 ml of 40% formaldehyde (formaldehyde:water, v:v).

A. 6 Nitric acid

Concentrated nitric acid.

A. 7 Para-dimethylaminobenzaldehyde (p-DMAB)

Add 2.0 g of p-DMAB to 50 ml of 95% ethanol and 50 ml of concentrated hydrochloric acid.

A. 8 Ferric chloride

Dissolve 2.0 g of anhydrous ferric chloride or 3.3 g of ferric chloride hexa-hydrate in 100 ml of distilled water.

A. 9 Froehde reagent

Dissolve 0.5 g of molybdic acid or sodium molybdate in 100 ml of hot concentrated sulfuric acid.

A. 10 Mecke reagent

Dissolve 1.0 g of selenious acid in 100 ml of concentrated sulfuric acid.

A. 11 Zwikker reagent

Solution A: Dissolve 0.5 g of copper (II) sulfate pentahydrate in 100 ml of distilled water.

Solution B: Add 5 ml of pyridine to 95 ml of chloroform.

A. 12 Simon's reagent

Solution A: Dissolve 1 g of sodium nitroprusside in 50 ml of distilled water and add 2 ml of acetaldehyde to the solution with thorough mixing.

Solution B: 2% sodium carbonate in distilled water.

Procedure: Add one drop of solution A to the drug, followed by two drops of solution B.

Validation of CSTs**Test color and specificity**

The drugs and other analytes were classified and prepared as either a drug standard, crystal, powder, tablet, or extract (Table 1). Drug standards were prepared in either chloroform or methanol at a concentration of 2.0 or 4.0 mg/ml (free-base). Crystals were tested without further processing. Tablets were crushed into a fine powder and leaf material was extracted with hexane. For all of the CSTs (except A.3), 500 µg of each analyte (125 or 250 µl of drug standard) was added to each of the three wells on the porcelain test plate. For the drug standards and extracts, the organic solvent was evaporated and the residue was reconstituted in 100 µl of chloroform before the CST was

Table 1 The classification of CST analytes

Analyte	Classification	Analyte	Classification
Acetaminophen	Drug standard	MDA HCl	Drug standard
Alprazolam	Drug standard	Meperidine HCl	Drug standard
Amobarbital	Drug standard	Mescaline HCl	Drug standard
Aspirin	Tablet	Methadone HCl	Drug standard
Baking soda	Powder	Methaqualone	Drug standard
Benzphetamine HCl	Drug standard	Methyphenidate HCl	Drug standard
Brompheniramine maleate	Drug standard	Morphine monohydrate	Drug standard
Chlordiazepoxide HCl	Drug standard	Nutmeg	Extract
Chlorpromazine HCl	Drug standard	Opium	Powder
Cocaine HCl	Drug standard	Oxycodone HCl	Drug standard
Codeine	Drug standard	Pentobarbital	Drug standard
Contac	Tablet	Phencyclidine HCl	Drug standard

D-Methamphetamine	Drug standard	Procaine HCl	Drug standard
Diacetylmorphine HCl	Drug standard	Propoxyphene HCl	Drug standard
Diazepam	Drug standard	Pseudoephedrine HCl	Drug standard
Dimethoxymethamphetamine HCl	Drug standard	Quinine HCl	Drug standard
Doxepin HCl	Drug standard	Salt	Crystals
Dristan	Tablet	Secobarbital	Drug standard
Ephedrine HCl	Drug standard	Sugar	Crystals
Exedrine	Tablet	Tea	Extract
Hydrocodone tartrate	Drug standard	THC	Extract
LSD	Drug standard	Tobacco	Extract
Mace	Crystals		

performed. The CST reagents were then added with a Pasteur pipette as described in [Section CST Procedures](#) for each test. For A.3, 500 µg of analyte was added to a glass culture tube. If organic solvent was present, it was evaporated and the test reagents were added as described for A.3. The final color was observed after 5 min and compared to reference colors in the Munsell and centroid color charts. Each analyte was tested in triplicate.

Drug detection limit

A working 1.0 µg/µl solution (or lower if necessary) of each analyte to be tested was prepared. The limit of detection (LOD) for each analyte was determined by testing serial dilutions of the working solution until the lowest concentration of analyte that was detectable in five replicates ($n=5$) was identified. This concentration was then multiplied by ten and recorded as the 'operational drug detection limit'. All tests were performed in the porcelain test plates except for A.3 which was performed in glass culture tubes.

Results and discussion

The CSTs are widely accepted as presumptive tests for drug detection. These CSTs provide information that allows the analyst to select the appropriate testing procedures to confirm the identity of the suspected drug. The information listed in the tables is intended as a guide for using CSTs and for preparing quality control materials for CSTs when they are performed in the laboratory or in the field. The actual color produced by the reagents for each drug may vary depending on many factors: the concentration of the drug, whether the drug is in salt or free base form, which salt form is present, any additional diluents or contaminants present in the sample, the color discrimination of the analyst, and the conditions under which the test is performed.

The original NIJ standards used centroid color charts published by the Inter-Society Color Council and the National

Bureau of Standards (ISCC-NBS) for color comparison. These charts include almost 270 colors logically grouped and listed numerically. However, these color standards are obsolete and are no longer considered to be an international standard for color description or comparison. Therefore, the ISCC-NBS numbers are listed for historical comparison purposes only. The ISCC-NBS charts have been replaced by the Munsell Color charts. The Munsell Book of Color (Volumes 1 and 2) is a master atlas of color that contains almost 1600 color comparison chips. The colors are prepared according to the specifications contained in the final report of the subcommittee of the Optical Society of America. Each page of the Munsell book presents one hue. There are 40 pages, each is 2.5 hue steps apart. On each page, the color chips are arranged by Munsell value and chroma. The standard way to describe a color using Munsell notations is to write the numeric designation for the Munsell hue (H) and the numeric designation for value (V) and chroma (C) in the form of H V/C. Since there are considerably more colors in the Munsell charts than in the centroid charts, two or more Munsell notations may correspond to the same previously used ISCC-NBS number.

Depending on the specificity of each color test, between 28 to 45 drugs or chemicals were tested in triplicate with each of the CSTs. For each CST, the final color resulting from a positive reaction with a known amount of analyte was compared to two reference color charts. These results are shown in [Table 2](#). Reference colors from the ICSS-NBS and Munsell charts were included along with a description of each final color.

A positive CST may indicate a specific drug or class of drugs is present in the sample, but the tests are not always specific for a single drug or class. For this reason, laboratories must rely on a battery of CSTs for the preliminary identification of an unknown drug. For example, Cobalt thiocyanate (A.1) is used to detect cocaine. However, many other drugs will also react with this reagent ([Tables 2](#) and [3](#)) and each analyte that tested

Table 2 Final colors produced by reagents A.1 through A.12 with various drugs and other substances

^aSubstances that gave no colors with these reagents are: D-galactose, glucose, mannitol, oregano, rosemary, and thyme.^bTea, mace, and nutmeg may interfere with the Duquenois test, but not the Duquenois-Levine modified test (A.3).

positive with cobalt thiocyanate produced a strong blue color. Also, the nitric acid test produced variations of yellow and orange colors with a variety of analytes including acetaminophen, diacetylmorphine, dimethoxymethamphetamine, and mescaline.

Six of the CSTs are indicated for the detection of opioids and other amines. These include Mandelin (A.4), Marquis (A.5), nitric acid (A.6), ferric chloride (A.8), Froehde (A.9), and Mecke (A.10) reagents. Unlike the cobalt thiocyanate reaction, different colors were produced with different drugs making it easier to presumptively identify the specific drug present. For example, a selected battery of tests to identify heroin (diacetylmorphine) might include the Mandelin, Marquis, and Froehde tests because they would produce reddish brown, deep purplish red, and purplish red colors, respectively. Codeine, a second opiate, could be identified with the same battery of CSTs because it produced olive, dark purple, and dark green colors, respectively. These three CSTs were reactive to many opioids with LODs as low as 1–5 µg, [Table 4](#), but as mentioned, the colors produced and the sensitivity was dependent on the many factors listed above.

Since positive reactions were dependent on the functional groups present in the chemical structure of the tested analytes, several of the CSTs were specific for certain classes of drugs. The *p*-DMAB reagent (A.7) reacted only with LSD, producing a deep purple color. This test had an LOD of 6 µg for LSD. Although mace, nutmeg, and tea reacted with the modified Duquenois-Levine test (A.3), as shown in [Table 2](#), only tetrahydrocannabinol (THC) produced a deep purple color that was extracted into chloroform. The Simon's test is reported to be specific for secondary amines like methamphetamine and MDMA. It did not react with ephedrine or pseudoephedrine because their structure contains an hydroxyl group that is in close proximity to the amine. Barbiturates can be detected by both the Dille-Koppanyi (A.2) and Zwikker (A.11) reagents. However, the Dille-Koppanyi test was more sensitive with LODs of 25 µg or lower whereas the LOD for phenobarbital with the Zwikker test was 1000 µg.

Conclusions

CSTs are valuable tools for the presumptive identification of drugs in unknown samples. These tests are very sensitive with LODs typically 1 to 50 µg depending on the CST and the analyte. The methods and validation procedures for 12 CSTs for use in the laboratory or in the field were described. For the identification of unknown drugs, reference colors from the Munsell and ICSS-NBS centroid color charts representing positive reactions for the 12 CSTs were included. Although these tests are sensitive and can be relatively specific, the actual color observed by the analyst performing the CST depends on many factors such as the concentration of the drug, whether the drug is a salt or free base, which salt form is present, the presence of contaminants in the sample, the color discrimination of the analyst, and the conditions under which the CST is performed.

Table 4 Drug detection limits^a

Reagent	Analyte	Drug detection limit (µg)
A.1	Cocaine HCl	60
A.1	Methadone HCl	250
A.2	Amobarbital	25
A.2	Pentobarbital	10
A.2	Phenobarbital	15
A.2	Secobarbital	25
A.3	THC	5
A.4	<i>o</i> -Amphetamine HCl	20
A.4	<i>o</i> -Methamphetamine HCl	100
A.4	Codeine	20
A.4	Diacetylmorphine HCl	20
A.4	Morphine monohydrate	5
A.5	<i>o</i> -Amphetamine HCl	10
A.5	Codeine	1
A.5	Diacetylmorphine HCl	10
A.5	LSD	5
A.5	Mescaline HCl	10
A.5	Methadone HCl	20
A.5	<i>o</i> -Methamphetamine HCl	5
A.5	Morphine monohydrate	5
A.6	Mescaline HCl	1
A.7	LSD	6
A.8	Morphine monohydrate	200
A.9	Codeine	50
A.9	Diacetylmorphine HCl	200
A.9	LSD	50
A.9	Mescaline HCl	100
A.9	Morphine monohydrate	25
A.10	Codeine	25
A.10	Diacetylmorphine HCl	200
A.10	LSD	50
A.10	Mescaline HCl	50
A.10	Morphine monohydrate	50
A.11	Phenobarbital	1000
A.12	<i>o</i> -Methamphetamine HCl	10
A.12	Methylphenidate HCl	300

^aThe solvent was chloroform except for A.8 which was methanol.
